LGMDR12 (LGMD2L; MIM 611307) is due to pathogenic variants in *ANO5*, which presents with late-onset leg weakness, with a mean age of onset of approximately 35 years. It should be suspected in individuals with late adult-onset proximal lower limb weakness, prominent asymmetry, calf myalgias or burning sensation, and markedly elevated CPK levels, typically 10 to 50 times the upper limit of normal. Muscle imaging usually presents with fatty replacement of the gastrocnemius medialis, soleus, and the posterior thigh muscles. Other phenotypes include a distal presentation (Miyoshi-like) and asymptomatic hyperCKemia with exercise induced myalgias. Cardiac involvement occurs in some individuals and usually manifests as cardiomyopathy, although in some cases, arrhythmias have been also reported. It is estimated to be one of the most common causes of LGMD. In the U.K. population, about 25% of LGMD cases are due to *ANO5* mutations. In the United States, LGMDR12 is the fourth most prevalent LGMD subtype.

Other Recessive Limb-Girdle Muscular Dystrophies

The remaining known recessive forms are considerably rarer.

LGMDR7 (LGMD2G; MIM 601954) is a very rare disorder linked to defects in *telethonin*, which is a muscle-specific protein localized to the Z-disc, associated with *titin*, and likely affecting sarcomere structure. LGMDR8 (LGMD2H; MIM 254110) is a relatively mild LGMD seen in Canadian Hutterites owing to a defect in *TRIM32*, which is likely involved in targeting proteins for proteasome degradation.

LGMDR10 (LGMD2J; MIM 608807) is a rare form of LGMD also known as *tibial muscular dystrophy*; it is caused by defects in the very large *TTN* gene. This sarcomeric protein has multiple proposed roles and directly interacts with numerous other proteins discussed in this section. Myofibrillar myopathy with respiratory failure and familial dilated cardiomyopathy 1G (MIM 603689; 604145) are other titinopathies. The recessive mutation can also produce forms of congenital myopathies or congenital titinopathies. Clinical features may include neck, and limb weakness, associated with joint contractures and spinal and chest wall deformities as well as early-onset respiratory insufficiency, and mild facial weakness. CPK levels varied within normal range to elevated. Interestingly, the muscle biopsy can show a variety of features, such as central nuclei, minicores, and/or dystrophic features. Due to the large size of this protein, depending on the differential splicing there are alternative isoforms of different length that will be expressed differently depending of the functional properties of each specific skeletal muscles. It also plays a key role in cardiac muscles where there are multiple mature isoforms. Several *TTN* mutations are associated with cardiomyopathy, including in particular truncating variants. The risk of cardiomyopathy in LGMDR10 is unclear.

LGMDR11, LGMDR13, LGMDR14, LGMDR15 and LGMDR24 (LGMD2K, LGMD2M, LGMD2N, LGMD2O; *POMGNT2*-related muscular dystrophy; MIM 609308; 611568; 613158; 613157) have defects of alpha-dystroglycan glycosylation due to mutations in *POMT1*, *FKTN*, *POMT2*, *POMGNT1* and *POMGNT2*, respectively. The LGMD presentation for these dystroglycanopathies includes early-onset limb girdle weakness, variable cognitive involvement with global developmental delay, and CPK levels 20 to 40 times normal. Most commonly, mutations in these genes present as CMD.

In the Turkish population, an ancestral founder mutation in *PLEC* causes LGMDR16 (LGMD2Q), which presents in early childhood as muscle weakness. Other *PLEC* mutations, however, cause epidermal bullosa simplex with late-onset muscular dystrophy or myasthenic syndrome with late-onset myopathy. *PLEC* encodes a scaffold protein critical for myofiber structure.

Previously named LGMD2R, *DES*-related muscular dystrophy is now considered part of the subgroup of distal myopathies, more specifically myofibrillar myopathy group. This reclassification also includes LGMD2V caused by pathogenic variants in *GAA* that caused Pompe disease, LGMD2W, and LGMD2Y. Currently, they have been reclassified to specific entities (*PINCH-2*–related myopathy and *TOR1AIP1*-related myopathy, respectively).

LGMDR21 (LGMD2Z) is associated with recessive mutation of *POGLUT1*. More than 20 patients have now been reported with this LGMD subtype. Onset ranges from congenital and early-onset symptoms to presentation in the fourth decade with primary respiratory complaints. All patients thus far have presented with limb girdle pattern of weakness. CK is mildly increased, muscle biopsy shows a moderate to severe dystrophic pattern, and muscle MRI is distinctive, with an "inside to outside" pattern of fatty degeneration that resembles the pattern seen with COL6-RD.

LGMDR22 and LGMDD5 are caused by mutations in three genes: *COL6A1*, *COL6A2*, *COL6A3*. They are most commonly known to produce a CMD form with a dominant or recessive inheritance pattern. LGMDR23 is due to recessive mutations in *LAMA2*, which more commonly cause MDC1A. The spectrum of LGMDR23 is quite wide, ranging from childhood onset resembling DMD or sarcoglycanopathies to milder phenotypes beginning in adolescence or adulthood. *LAMA2* encodes the laminin alpha-2 protein, and there is a direct correlation with residual laminin alpha-2 expression and the severity of the disease. COL6-RD and MDC1A are presented in detail in the section on CMDs.

LGMDR25 (LGMD2X) is caused by loss of function variants in *BVES*, encoding the Popeye domain containing protein 1 (POPDC1). This is a mild LGMD with onset between the second and the third decade associated with frequent episodes of syncope due to AV block requiring pacemaker placement in most cases. Other features include elevated CK (within 1,000-3,000 IU/L) and exercise induced myalgias.

Autosomal Dominant Limb-Girdle Muscular Dystrophy

Dominant forms are less common (10% of LGMD), are typically milder in clinical severity, and are associated with substantial clinical heterogeneity. As described as below and in subsequent sections, several subtypes previously considered as forms of dominant LGMD have now been reclassified into other muscle disease categories.

Limb-Girdle Muscular Dystrophy 1A

LGMD1A is rare and linked to defects in myotilin localized to the Z-disc near telethonin. Affected members are described as having a distinctive, dysarthric speech pattern. This disorder has now been reclassified as a myofibrillar myopathy within the distal myopathies.

Limb-Girdle Muscular Dystrophy 1B

LGMD1B is a result of mutations in the *LMNA* gene that encodes both lamin A and lamin C, which are alternative splice forms. Currently, it has been reclassified as autosomal dominant EDMD. *LMNA* mutations are also seen in hypertrophic cardiomyopathy, familial partial lipodystrophy, CMT2C, mandibuloacral dysplasia, and Hutchinson-Gilford progeria. The LGMD phenotype is relatively mild but often has significant cardiomyopathy and cardiac conduction disease similar to EDMD; some also have contractures but less severely than in EDMD.

Limb-Girdle Muscular Dystrophy 1C

Mutations in caveolin-3 (*CAV3*) cause LGMD1C. This disorder has been reclassified as rippling muscle disease. In addition, *CAV3* mutations can cause asymptomatic hyperCKemia and a form of distal myopathy. The dystrophic form of the disease often begins around age 5 years with cramping, mild weakness, and calf hypertrophy, but mild cases without clinical weakness are also seen. Caveolin-3 is a component of plasma membrane vesicular invagination structures important for cellular trafficking and signaling. CAV3 interacts with dysferlin, and in some patients with dysferlinopathy, there is a secondary reduction in CAV3 levels.

Limb Girdle Muscular Dystrophy 1D

LGMDD1 (MIM 611332) previously known as LGMD1E is caused by pathogenic variants in *DNAJ6B*. The initial phenotype encompassed an adult onset LGMD with slow progression. This phenotype is usually caused by mutations in the C-terminal. N-terminal variants produce a different phenotype

with earlier onset and distal involvement with more severe compromise of the respiratory and bulbar muscles. Muscle biopsy shows autophagic vacuoles on the center of the fiber or over the subsarcolemmal region, associated with internalized nuclei and variability on the fiber size. CPK is typically normal or slightly elevated but may be increased up to 3,000 IU/L.

Limb-Girdle Muscular Dystrophy D2

LGMDD2 (MIM 610032) is associated with mutations in *TNPO3*, found in a large Spanish family with variable juvenile to adult-onset muscular dystrophy. *TNPO3* encodes Transportin 3, a nuclear protein that is a member of the importin-beta/transportin family. Muscle biopsies in the Spanish patients showed abnormally enlarged nuclei increased mitochondria and filamentous structures observed in electron microscopy. Several other reports have described a similar phenotype.

LGMDD3 (MIM 607137) is caused by mutations in *HNRPDL*. It was identified in a Brazilian family with 12 individuals affected with slowly progressive proximal muscle weakness of variable onset (late teens to early adulthood). All patients developed type 2 diabetes after the fourth decade. Another feature present was weakness of toes and finger flexors. CPK usually is elevated (up to 10-fold above the upper normal limit). A later report contributed an additional Uruguayan family where some members developed early cataracts.

Limb-Girdle Muscular Dystrophy 1G Through Limb-Girdle Muscular Dystrophy 1H

These disorders are chromosomally mapped forms awaiting gene identification.

Differential Diagnosis

The differential diagnosis for LGMDs requires important consideration of age and clinical presentation plus any ancillary diagnostic data. For the "Duchenne-like" LGMDs (sarcoglycanopathies and dystroglycanopathies), which present with symptoms in the first decade and have a relentlessly progressive course like DMD/BMD, the key disorders to consider are DMD, type 3 SMA, and late infantile Pompe disease. Other considerations (particularly when the CPK is normal or only mildly elevated) are certain subtypes of congenital myopathy and congenital myasthenic syndrome. Lastly, inflammatory myopathies (especially anti HMGCR myopathy in pediatric cases) provide an important, and potentially treatable, differential diagnosis.

Management

Treatment presently is supportive in nature for essentially all subtypes, as meaningful disease-modifying therapies have yet to enter the clinic. As with other types of muscular dystrophy, key management considerations relate to support of motor function (mobility assistance ranging from canes to wheelchairs), respiratory care (bilevel positive airway pressure, for example, when nocturnal hypoventilation or sleep apnea develop), cardiac care (cardiomyopathy occurs in some subtypes), and orthopedic management (for scoliosis). Lifespan is not impacted in many of the subtypes. Important exceptions include the sarcoglycanopathies, which have progressive symptomatology leading respiratory failure, and, in some cases, fatal cardiac disease.

OCULOPHARYNGEAL MUSCULAR DYSTROPHY

OPMD is a late-onset autosomal dominant disorder with progressive ptosis, dysphagia, and late-onset proximal limb weakness. Autosomal recessive forms are known. Although originally recognized in French Canadian families, cases have been recognized worldwide. The bulbar onset, is usually confused with myasthenia gravis rather than other myopathies. Muscle filamentous intranuclear inclusions are a pathologic hallmark, but rimmed vacuoles are also prominent. The CPK is normal or mildly elevated. The disease maps to 14q11.2-q13 and is caused by an expanded GCG repeat in the polyadenylation-binding protein 2 (*PABP2*). The disease-producing repeat number is unusually short. The normal repeat length is 6, and disease results from lengths of 7 to 13, most commonly 9 and 10 repeats. A more severe autosomal recessive phenotype with earlier onset is described in homozygous patients. *Oculodistal muscular dystrophy* is even less common than OPMD and differs in the distribution of limb weakness, the genetic locus has not yet been mapped.

OTHER RARE DYSTROPHIES

Several forms of scapuloperoneal weakness with dystrophic muscle pathology are not linked to the FSHD site. Some show hyaline bodies. Autosomal dominant and recessive and X-linked–dominant inheritance patterns are described. A similar phenotype is neurogenic (scapuloperoneal muscular atrophy). Mutations in the *FHL1* gene cause reducing body myopathy, and a milder phenotype called X-linked dominant scapuloperoneal myopathy. Desmin and myosin heavy-chain 7 gene mutations have been identified in autosomal dominant cases. Other rare discrete entities include epidermolysis bullosa simplex with late-onset muscular dystrophy linked to plectin gene mutations and desmin-related myopathy, one with a defect in the α-β crystalline gene on 11q as well as dominant and recessive forms linked to the desmin gene on 2q. Despite all of the identified genetic defects, additional forms of LGMD will be linked to yet unidentified chromosomal loci and novel pathogenic genes.

Distal Myopathies (Distal Muscular Dystrophies)

Distal myopathies (distal muscular dystrophies) are defined by clinical manifestations in the feet and hands preceding proximal limb weakness. As heritable diseases with features of myopathy and slow progression, they are properly considered muscular dystrophies. The distinction from hereditary neuropathies is supported by spared sensation and histologic and electrodiagnostic features of myopathy. Most distal myopathies have been assigned to different chromosomal positions, confirming the clinical differences in patterns of inheritance, onset in leg or hands, predominant leg weakness in anterior or posterior compartments, presence or absence of vacuoles on muscle biopsy, and serum CPK levels.

The most common form is *Welander distal* myopathy (MIM 604454), which was first described in Sweden; inheritance is autosomal dominant. Symptoms begin in adolescence or adult years and progress slowly. The legs are affected before the hands.

Histologic changes are mild, but filamentous inclusions may resemble those seen in OPMD or inclusion body myositis. Serum CPK is only slightly elevated.

In the autosomal recessive *Nonaka* variant (MIM 605820), a vacuolar myopathy is seen, the gastrocnemius muscles are spared, and serum CPK values are only slightly increased. Nonaka distal myopathy and hereditary inclusion body myopathy share clinical and morphologic similarities; both conditions are a result of defects in the UDP-*N*-acetylglucosamine 2-epimerase/*N*-acetylmannosamine kinase (*GNE*) gene. *Miyoshi* (MIM 254130) distal myopathy is also autosomal recessive but differs from Nonaka in that the histologic changes are nonspecific (without vacuoles), the gastrocnemius muscles are affected first, and serum CPK values are notably elevated; hyperCKemia may be noted before symptomatic weakness. Miyoshi myopathy and LGMDR2 (proximal limb weakness) are allelic, map to 2p17, and are associated with mutations in *DYSF* (see Fig. 147.1). Miyoshi type 3 is due to *ANO5* mutations. Some Miyoshi families do not have mutations in either gene, which implies further locus heterogeneity. Other variants of distal myopathies have been described and more are likely to be identified.

NONDYSTROPHIC MYOPATHIES—CONGENITAL MYOPATHIES

Definitions

Congenital myopathies are a clinically and genetically heterogeneous group of conditions that have historically been identified and defined by features on muscle biopsy in the context of clinically apparent muscle disease (see Fig. 147.2). The general histopathologic definition encompasses both a lack of dystrophic findings on muscle biopsy and instead the observation of one of a range of nondystrophic changes. Such changes include the presence of excessive central nuclei (when >25% and seen in the absence of other pathology, termed *centronuclear myopathy*), the observation of nemaline rods or bodies (best seen on Gomori trichrome and verified with electron microscopy and suggestive of a diagnosis of NM), the existence of cores or core-like lesions (best appreciated with oxidative stains and often categorized as central core disease (CCD) or minicore myopathy depending on the specific appearance), and the finding of selective type I myofiber smallness in the absence of other features defining a specific congenital myopathy called congenital fiber-type disproportion. Additional abnormalities have been described, such as caps and zebra bodies, and in all, there are dozens of different categorizations of congenital myopathies derived from these biopsy observations. Additionally, it should be noted that some congenital myopathy patients show muscle replacement with fibrous and fatty tissue with increasing age, despite the lack of active muscle degeneration on muscle biopsy.

With the broad application of genetic testing, the definition of congenital myopathy is shifting. It now includes consideration of not only biopsy findings but also clinical features and genetic testing results. In many cases, patients no longer require muscle biopsy data to support their diagnosis, and the condition is instead defined based on gene mutation in the context of clinical symptoms. For example, a severely weak male infant with an underlying causative mutation in *MTM1* would be considered to have XLMTM even if he has not had a muscle biopsy or if a muscle biopsy did not show the classic features of XLMTM. Of note, mutations in more than 20 genes have been identified to cause congenital myopathy (Table 147.3) (Fig. 147.9).

Epidemiology

Establishing the true incidence and prevalence of congenital myopathies has been a challenging undertaking because it requires population-based assessment and must take into account the possibility of missed diagnoses and the fact that patients may present outside of the early childhood period. That said, there have been attempts to define these numbers, with one comprehensive study from a single U.S. state documenting a point prevalence of 1:26,000. This number is likely an underestimate due to underascertainment, and the true prevalence is probably closer to 1:10,000 (based on fraction of patients seen in typical pediatric neuromuscular clinic when compared to disorders with known prevalence such as DMD and SMA). In terms of subtype prevalence based on genetics, *RYR1*-related myopathies (ie, myopathies due to *RYR1* mutations) are by far the most common. In one study examining a large U.K. cohort, *RYR1* mutations were found in more than half the genetically solved cases. Other frequently encountered genetic subtypes include *TTN*, *ACTA1*, *SEPN1*, *NEB*, and *MTM1*. *TTN* mutations in particular are emerging as being nearly as common as *RYR1*. In terms of prevalence based on histopathology, core myopathies are the most common, reflecting the association between *RYR1* mutations and core-like lesions. NM is the next most common, followed closely by CNM.

Diagnosis

Given the setting of a suggestive clinical picture, the establishment of a definitive diagnosis of congenital myopathy comes from either a positive genetic test for a known myopathy gene or a muscle biopsy with one of the recognized histopathologic patterns (eg, centronuclear, nemaline, core). Although not systematically examined, based on available literature and anecdotal experience, genetic testing (via multigene panel or whole exome sequencing) identifies an etiology in approximately two-thirds of cases. Other supportive diagnostic studies include laboratory investigations, EMG, and muscle MRI. CPK values are typically normal, although elevated CPKs have been found in some cases (eg, some *RYR1* and *SEPN1* cases), and a high CPK cannot be used to exclude a diagnosis of congenital myopathy. Other laboratory studies have little value in terms of providing a positive diagnosis; screening metabolic laboratories, for example, have essentially no diagnostic yield. Muscle biopsy, the historic standard for congenital myopathies, is now considered second line after genetic testing in most situations. Biopsy can be essential to clarify cases when genetic testing is ambiguous (such as when a variant of unknown significance is found) or to help establish a diagnosis when genetic testing in not revealing. In critically ill neonates, a biopsy can be obtained rapidly and thus help clarify diagnosis before genetic testing results are reported. Muscle MRI is an emerging modality that has been looked at for several subtypes, and there are important patterns associated with specific genetic causes. MRI therefore can provide a useful adjunct to clarify cases where variants of unknown significance are identified or when a specific mutation eludes diagnosis on next-generation sequencing panels or whole exome sequencing. Important differential diagnoses include congenital myasthenic syndrome, CMD (and LGMDs in older children), mitochondrial disease, and spinal muscular atrophy.

TABLE 147.3 Genetic Subtypes of Congenital Myopathies[a]

Gene	Subtype	Inheritance Pattern	Protein	Primary Subcellular Involvement	Possible Pathogenesis
ACTA 1	• NM	AD, AR	Actin, α_1, skeletal muscle	Thin filament involvement	Abnormal thin filament structure
	• Cap disease (NM variant)	AD			
	• Zebra body myopathy (NM variant)	AD			
	• Congenital fiber-type disproportion	AD			
TPM3	• NM variant	AD, AR	Tropomyosin 3		
	• Cap disease (NM variant)	AD			
	• Congenital fiber-type disproportion	AD			
TPM2	• NM	AD	Tropomyosin 2 (β)		
	• Cap disease (NM variant)	AD			
TNNT1	• NM	AR	Troponin T type 1 (skeletal, slow)		
NEB	• NM	AR	Nebulin		Thin filament remodeling +/– stability
	• Core-rode myopathy	AR			
LMOD3	• NM	AR	Leiomodin 3		
KBTBD13	• NM	AD	Kelch repeat and BTB (POZ) domain containing protein 13		
CFL2	• NM	AR	Cofilin 2 (muscle)		
KLHL40	• NM	AR	Kelch-like family member 40		
KLHL41	• NM	AR	Kelch-like family member 41		
MYO18B	• NM	AR	Myosin 18B	Unknown	Unknown
RYR1	• Central core myopathy	AD, AR	Ryanodine receptor 1	Triad involvement	Abnormal EC coupling
	• Multiminicore myopathy	AR			
	• Core rod myopathy	AD, AR			
	• NM	AR			
	• Congenital fiber-type disproportion	AR			
	• Centronuclear myopathy	AR			
	• Congenital neuromuscular disease with uniform type 1 fiber	AD			
CACNAS1	• Congenital fiber-type disproportion	AR	DHPR		
STAC3	• Native American myopathy	AR	SH3 and cysteine-rich domain-containing protein 3		
ORAI1	• Tubular aggregate myopathy	AD	Transmembrane protein 142A		Abnormal SOCE
STIM1	• Tubular aggregate myopathy	AD	Stromal interaction molecule 1		
SEPN1	• Multiminicore myopathy	AR	Selenoprotein N1		Oxidative defects
	• Congenital fiber-type disproportion	AR			
CCDC78	• Centronuclear myopathy	AD	Coiled coil domain containing protein 78		Abnormal EC coupling
BIN 1	• Centronuclear myopathy	AR, AD	Amphiphysin		Membrane remodeling +/– stability
DNM2	• Centronuclear myopathy	AD	Dynamin 2		
MTM1	• Myotubular myopathy	XR	myotubularin		
SPEG	• Centronuclear myopathy with dilated cardiomyopathy	AR	SPEG complex locus		
PTPLA (HACD1)	• Congenital myopathy related to PTPLA	AR	Protein tyrosine phosphatase-like A (3-hydroxyacyl-CoA dehydratase 1)		
TTN	• Centronuclear myopathy	AR	Titin		
	• Congenital myopathy with fatal cardiomyopathy	AR			

TABLE 147.3 Genetic Subtypes of Congenital Myopathies[a] *(continued)*

Gene	Subtype	Inheritance Pattern	Protein	Primary Subcellular Involvement	Possible Pathogenesis
MYH7	• Myosin storage myopathy	AD	Myosin, heavy chain 7, cardiac muscle		Abnormal ATPase and actin-binding properties; structural abnormalities
	• Myosin storage myopathy with cardiomyopathy	AR			
	• Congenital fiber-type disproportion	AD			
MYH2	• Myosin IIa myopathy	AD, AR	Myosin, heavy chain 2, skeletal muscle	Heavy chain	Abnormal ATPase and actin-binding properties
CNTN1	• Compton-North congenital myopathy	AR	Contactin 1	NJ	Structural abnormalities; aberrant NJ adhesion
MEGF10	• Early-onset myopathy, areflexia, respiratory distress, and dysphagia	AR	Multiple EGF-like domains 10	Satellite cells	Abnormal regulation of satellite cells
	• Minicores	AR			
ZAK	• Congenital fiber-type disproportion	AR	Sterile alpha motif and leucine zipper containing kinase AZK	Unknown	Mitogen-activated protein kinase signaling pathway

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; ATPase, adenosine triphosphatase; CoA, coenzyme A; DHPR, dihydropyridine receptor; EC, excitation contraction; EGF, epidermal growth factor; NJ, neuromuscular junction; NM, nemaline myopathy; SOCE, store-operated calcium entry; XR, X-linked recessive.

FIGURE 147.9 Skeletal muscle proteins and congenital myopathies. The triad is a structure formed by the apposition of the T tubule and the sarcoplasmic reticulum (SR). Prompted by signals from the neuromuscular junction, its depolarization allows the release of calcium from the SR (via the ryanodine receptor, RyR1) into the cytoskeleton (a process called excitation contraction coupling). The thin filaments are composed primarily of skeletal muscle actin as well as the accessory proteins nebulin, troponin, and tropomyosin. Each actin molecule has a binding site with the myosin head (which compose the thick filament). Each troponin molecule has a binding site for calcium. In the presence of calcium release from the SR during excitation contraction coupling, the troponin binds calcium and moves tropomyosin to allow the cross-bridge binding of actin with the myosin head to produce a muscle contraction. The energy for the contraction is provided by adenosine triphosphate generated from the mitochondria. The thin filaments are anchored to the Z band in part by titin, which also serves a molecular spring for the myofiber, which enables it to provide passive resistance to contraction of the sarcomere. Within brackets are the congenital myopathies that result from mutations of the proteins that function at the various muscle substructures. (Adapted by permission from Dowling JJ, Gonorazky HD, Cohn RD, Campbell C. Treating pediatric neuromuscular disorders: the future is now. *Am J Med Genet A*. 2018;176[4]:804-841.)

X-Linked Myotubular Myopathy

XLMTM is caused by a pathogenic mutation in the *MTM1* gene. The typical clinical presentation is one of severe neonatal hypotonia and weakness, including respiratory failure and challenges with oral feeding. Boys with XLMTM additionally have prominent facial weakness and ophthalmoparesis (which may be hard to detect in affected infants). Some patients will have a distinctive overall appearance that includes prominent eyes, elongated facies, dolichocephaly, long tapered fingers, and increased growth parameters (particularly when compared to other congenital myopathy patients) (Fig. 147.10). About 25% of XLMTM patients die in the first year of life. Survivors have significant support needs, with the majority requiring tracheostomy and mechanical ventilation, G-tube feeding, and wheelchair assistance for mobility. After the age of 2 years, the mortality rate is approximately 10% per year; few patients with classic XLMTM reach adulthood. The main cause of death is respiratory failure (acute on chronic), although rarely, patients experience sudden and fatal liver hemorrhage due to a condition called hepatic peliosis. Of note, XLMTM does not affect the heart directly. It is also not thought to cause cognitive impairment, but this has not been adequately studied, and recent comprehensive natural history studies suggest learning impairment may manifest in some patients.

Historically, XLMTM was defined based on suggestive muscle biopsy findings, with a pattern typical of CNM. These include myofiber hypotrophy, increased central nuclei, and a distinctive alteration of oxidative stains, with accumulation in the center of the fiber. On electron microscopy, there is depletion of triads, and triad pathology is considered a main driver of disease pathogenesis. A definitive diagnosis is considered only in cases where an *MTM1* mutation is identified. Myotubularin is a lipid phosphatase that acts in the endosome to dephosphorylate phosphoinositides. Mutations are most commonly loss of function, including nonsense, frameshift, and rearrangements (deletions and duplications). Missense mutations are also found, with some missense and splice site changes resulting in a milder phenotypic presentation. This milder phenotype accounts for about 10% to 15% of cases, and affected individuals usually achieve the ability to ambulate and do not require daytime ventilatory support. The *MTM1* gene is located on the X chromosome; as such, most patients are males. There are rarely severely manifesting carrier females who present in infancy or early childhood. There are also underrecognized clinical manifestations in "healthy" carrier females, including exercise intolerance, mild progressive weakness, myalgias, facial weakness, and ophthalmoparesis. Weakness in affected females is often asymmetric.

FIGURE 147.10 X-linked myotubular myopathy. Individual with X-linked myotubular myopathy due to mutation in the *MTM1* gene. This photo presents classical features of the disease, including ptosis, fixed eye positioning (indicative of ophthalmoparesis), facial weakness, reduced muscle bulk, and respiratory insufficiency requiring tracheostomy and invasive ventilation.

Management of XLMTM currently centers on supportive care, with critical attention to respiratory function and preservation of respiratory reserve. Pyridostigmine has been shown in preclinical models and in case reports to improve the XLMTM phenotype, although its impact on patients has not been systematically examined. Several therapies are on the cusp of clinical care, having been shown to be effective in improving muscle structure and function and animal survival in animal models of the disease. Gene replacement therapy is currently being tested in clinical trial, and preliminary data from the trial have been extremely promising. Other potential therapeutic strategies include lowering dynamin-2 (either with tamoxifen or via antisense oligonucleotide) and inhibition of the partnering lipid kinase.

Other Centronuclear Myopathies

CNM is an umbrella diagnosis that includes all myopathies with muscle biopsy findings that include >25% central/internal nuclei in the absence of dystrophic changes. In addition to XLMTM, mutations in five other genes have been found in conjunction with CNM pathology (*RYR1*, *DNM2*, *BIN1*, *SPEG*, and *TTN*). Mutations in *RYR1* and *TTN* are common causes of congenital myopathy in general, and CNM pathology is found in only a fraction of the overall cohort. Heterozygous *DNM2* mutations are the most common cause of autosomal dominant CNM. In addition to the classic features of CNM on biopsy, *DNM2* patients also have a distinctive "spoke on wheel" pattern with oxidative stains. Recessive causes include mutations in *RYR1*, *TTN*, *BIN1*, and *SPEG*. Histopathology in *RYR1* CNM may resemble XLMTM, whereas pathology in *BIN1* may look like that seen with *DNM2* CNM, with the additional feature of clumps of several internal nuclei in individual fibers. Of note, all of the CNM genes are included on multigene congenital myopathy panels, and thus, many patients are now diagnosed based on genetics alone.

There is a broad range of clinical symptomatology associated with non-XLMTM CNM. Although the spectrum of severity spans from neonatal lethality to adult onset, an overall distinguishing clinical feature of CNM as compared to other congenital myopathies is ophthalmoparesis. This is seen in all subtypes except for titinopathies. Patients with *RYR1*-related CNM tend to have severe weakness that can phenocopy XLMTM. *BIN1* and *SPEG* mutations are rare and also may be seen with neonatal onset disease; patients with *SPEG*-related CNM may have severe cardiomyopathy, and it is the only subtype documented to manifest primary heart disease. *TTN*-related CNM is typically milder with childhood onset and the ability to achieve ambulation. *DNM2*-related CNM is bimodal in distribution, with a neonatal onset form (less severe than XLMTM) and a milder form that presents in adolescence and early adulthood. There are clear genotype-phenotype correlations that account for this.

Currently, there are no dedicated therapies for the non–X-linked forms of CNM, and management is strictly supportive. As with XLMTM, and supported by preclinical data and patient case reports, pyridostigmine is used off-label by many patients with CNM. Unlike XLMTM, the therapeutic pipeline contains fewer potential therapies. In addition, the natural history is poorly defined, and suitable outcome measures have yet to be defined.

Nemaline Myopathy

NM encompasses a group of genetically heterogeneous muscle diseases unified by the observation of nemaline rods or nemaline bodies on muscle biopsy. Rods are best visualized with modified Gomori trichrome and have a distinctive appearance on electron microscopy. Clinically, NM can be broken down into categories based on clinical severity. These include severe congenital (16%), intermediate congenital (20%), typical congenital (46%), childhood onset (13%), and late onset (4%). The most striking clinical feature in NM regardless of subtype is usually lower facial and bulbar weakness, resulting in a distinctive myopathic facial appearance and impairments with speech and swallowing. Weakness tends to be more axial than appendicular and is associated with scoliosis (often severe) and respiratory failure (most typically nocturnal hypoventilation and sleep apnea). Mutations in at least 14 genes have been associated with NM. As with other myopathy subtypes, genetic testing is often pursued before muscle biopsy, and the evolving definition of NM includes cases with consistent gene mutations without a supporting muscle biopsy.

The severe congenital form often results in neonatal lethality and is on the differential for fetal akinesia syndrome. This is the only NM category with significant associated mortality. Heterozygous mutations in *ACTA1* are the most likely to result in the severe form, although *ACTA1* mutations present a wide range of clinical phenotypes. Biallelic/recessive mutations in *KLHL40*, *KLHL41*, and *LMOD3* are rare but nearly always are associated with severe or intermediate congenital forms. *LMOD3* NM is the only subtype with frequent ophthalmoparesis. Typical congenital myopathy presents with neonatal hypotonia and weakness. Extremity weakness is largely nonprogressive, and individuals typically achieve ambulation and may even show gains in strength after infancy. Persistent disability relates mainly to bulbar dysfunction and axial symptoms (neck flexor contractures, scoliosis, nocturnal respiratory failure). Biallelic/recessive mutations in *NEB* are the most common cause of typical congenital NM and overall the most common cause of NM, accounting for approximately 50% of cases. Other genetic causes for typical congenital NM include heterozygous mutations in *ACTA1*, *TPM2*, and *TPM3*. Of note, the adult-onset form of NM refers primarily to sporadic late-onset NM, an autoimmune disease that will not be discussed further in this section.

ACTA1 mutations are the second most common cause of NM. Mutations are almost always dominant missense variants, although recessive actinopathies have been reported. Mutations are found throughout the gene, and the ACTA1 protein is extremely intolerant to changes in its amino acid sequence. There is an extremely broad range of clinical severity associated with *ACTA1* mutations including notable intra- and interfamilial variation for similar mutations. The explanation for this variability is not clear but may relate either to the ratio of mutant to wild type protein or to the level of expression of the highly homologous cardiac actin isoform. Recessive actinopathies are compatible with life due to the predominant expression of the cardiac isoform during early fetal development and disease severity is inversely correlated with the postnatal level of expression of cardiac actin. Mutations can also be seen with several different histopathologic subtypes, including rods, cores, cores and rods, and fiber-type disproportion as well as rare findings such as caps and zebra bodies.

ACTA1 encodes filamentous skeletal muscle actin, the core component of the sarcomeric thin filament. *NEB* encodes nebulin, a giant protein that associates with actin, and has been shown to dictate thin filament length. *TPM2* and *TPM3* encode tropomyosins that function at the actin-myosin cross bridge; *LMOD3* is also part of this structure. Other NM genes, such as *KLHL40* and *KLHL41*, which are involved in protein ubiquitination, serve to modulate thin filament stability. In total, based on the known function of these genes and the impact of mutations, the unifying pathomechanism underlying NM is dysfunction of the structure/function of the thin filament, with a resulting consequence being reduced force generation and muscle weakness.

At present, there are no disease-modifying therapies for any NM subtype. Supportive care is as with other congenital myopathies, with an emphasis on targeted management of the severe bulbar dysfunction observed in many individuals. L-tyrosine has been reported in a case series to reduce salivation and improve speech and swallowing in some patients but results in the broad NM population are mixed at best. There are a limited number of therapeutic candidates in the development pipeline for NM, perhaps owing to the fundamental function of the thin filament and the challenge in finding modifiers for alterations in its structure and activity. There is also a need for systematic examination of disease natural history and identification of outcome measures suitable for interventional clinical trials.

Core Myopathies—RYR1-Related Myopathies

RYR1-related myopathies are the most common subtype of congenital myopathy. In some populations, the prevalence of pathogenic *RYR1* variants is thought to be as high as 1:10,000. Mutations in *RYR1* manifest an extremely broad range of clinical presentations and histopathologic features. The classic disorder associated with heterozygous missense mutations is CCD, named for the characteristic absence of staining seen with oxidative stains on muscle biopsy. Patients with CCD tend to have mild/moderate extremity weakness that is nonprogressive, although occasionally, individuals can present with severe symptoms starting at birth that can result in respiratory failure and even early death (**Fig. 147.11**). Another classic disorder associated with heterozygous *RYR1* variants is MH, a pharmacogenetic condition precipitated by volatile anesthetics and that is characterized by fever, muscle rigidity, and fulminant muscle breakdown. Some patients will have both CCD and MH. Other clinical conditions linked to heterozygous variants are exertional rhabdomyolysis, myalgias with exercise intolerance, periodic paralysis, and heat stroke.

An approximately equal proportion of cases are caused by recessive/biallelic mutations in *RYR1*. Patients with recessive *RYR1*-related myopathy tend to have an overall more severe clinical picture as compared to patients with heterozygous/dominant mutations. The recessive *RYR1*-myopathy phenotype often includes diffuse weakness with extraocular and facial muscle weakness. All motor domains are usually impacted, and affected individuals are often wheelchair and ventilator

FIGURE 147.11 Central core disease. Photograph of an individual with central core disease (as established by muscle biopsy) and a de novo heterozygous mutation in the *RYR1* gene. Key features of the disease illustrated in this picture include mild lower facial weakness, respiratory muscle weakness (as evidenced by the presence of a tracheostomy), muscle hypotrophy, and chest wall skeletal deformity.

dependent, although there is a range of severity that is correlated in many cases with the type of *RYR1* mutations. Specifically, patients with nonsense or frameshift mutations tend to have a more severe disease compared to individuals with two missense variants. In terms of histopathology, central cores are only rarely encountered in recessive cases; instead, biopsies are characterized by a range of findings including multiminicores, core-like lesions, central nuclei, and/or fiber-type disproportion. Correlations between histotype and phenotype are not fully defined, nor is the relationship between histotype and genotype.

RYR1 is a large gene with 106 exons that encodes the ryanodine type I receptor (RyR1). RyR1 is a calcium channel located at the terminal sarcoplasmic reticulum. It is a key component of the excitation contraction apparatus and an important contributor to intracellular calcium homeostasis in skeletal muscle. Mutations are located throughout the gene. There are three "hotspots" for missense mutations where the majority of the mutations associated with either CCD or MH or their combination are found. Mutation consequence falls into four broad categories: leading to reduced levels of RyR1 protein, resulting in impaired release of calcium from the sarcoplasmic reticulum, causing chronic calcium leak, and leading to hyperexcitability to various stimuli (such as volatile anesthetics or heat).

Clinical management is dictated by disease severity and the presence of dynamic symptoms. For example, individuals with mutations with expected MH susceptibility should be given appropriate anesthetic precautions, although in practice, most/all patients with *RYR1* mutations are considered as MH susceptible. MH reactions are treated intraoperatively with dantrolene. Individuals with exercise intolerance, exertional rhabdomyolysis, and heat illness are cautioned to avoid certain conditions (such as avoiding exertion on hot days); there is some case study evidence for use of dantrolene to improve exercise tolerance and reduce myalgias. For patients with static symptoms, care is anticipatory and related to maintenance of respiratory function and support for extremity muscle weakness. Skeletal problems are common, including chest wall deformities and progressive scoliosis, and scoliosis surgery is often required. Importantly, other organ systems are not affected in *RYR1* myopathy; there is no evidence of cardiac involvement, and cognitive function is intact.

Currently, there are no disease-modifying treatments other than dantrolene for MH. Aberrant oxidative stress has been found in both preclinical models and in patients. However, a clinical trial evaluating the antioxidant N-acetyl cysteine did not show clinical benefit. Additional therapeutic strategies, such as drugs (eg, Rycals) that improve RyR1 calcium release, are in development; in parallel, work to establish a better understanding of disease natural history is ongoing. Of note, RyR1 interacts with the dihydropyridine receptor to help regulate excitation contraction coupling in the muscle. Mutations in a subunit of this receptor, *CACNA1S*, cause muscle diseases with substantial phenotypic overlap to *RYR1*-related myopathies. These include MH susceptibility (with heterozygous *CACNA1S* mutations) and a severe myopathy with core like lesions due to recessive mutations.

Core Myopathies—SELENON-Related Myopathy

The other major cause of core myopathy is recessive mutations in the *SELN* gene, previously known as *SEPN1*. *SELN*-related myopathy is associated with several histotypes including minicore myopathy (most common), Mallory body myopathy, congenital fiber-type disproportion, and rigid spine muscular dystrophy. Despite these range of pathologic changes, the phenotype is generally uniform and is characterized by axial weakness with severe neck flexion weakness, contractures, rigid spine, and progressive scoliosis, with relative sparing of the extremity muscles, fitting overall with so-called rigid spine syndrome. Respiratory insufficiency is severe and progressive with patients often requiring nocturnal and eventually daytime noninvasive ventilatory support while remaining ambulant.

SELN encodes the SELENON protein, a selenocysteine containing cytoplasmic protein that has an important role in regulating oxidative stress in skeletal muscle fiber. Disease pathogenesis is likely related to impaired ability of the myofiber to buffer pro-oxidants and free radicals, which cause subsequent damage. A logical potential therapeutic strategy therefore for *SELN*-related myopathy is antioxidant therapy; preclinical studies (in mice and patient cells) support this approach. A clinical trial of *N*-acetylcysteine is in progress.

Management at present in *SELN*-related myopathy focuses on optimization of respiratory function, monitoring of scoliosis, and eventual scoliosis surgery. Respiratory insufficiency and scoliosis are progressive and can often worsen rapidly. Despite these severe comorbidities, and the recognizable nature of the condition, there appears to be substantial underdiagnosis of *SELN*-related myopathy. This assertion is backed by estimations based on mutational frequency in the general population.

TTNopathies

An emerging group of myopathies are due to mutations in *TTN*, one of the largest genes in the genome. Heterozygous (typically truncating) mutations in *TTN* are known to be a common cause of dilated cardiomyopathy. *TTN*-related skeletal myopathy (or TTNopathy) has only recently come to the fore, largely due to improvements in sequencing technology and the ability to comprehensively and accurately examine the whole *TTN* gene in a cost-effective manner. TTNopathy is likely to be the second most common form of congenital myopathy after *RYR1*-related myopathy.

The clinical spectrum of TTNopathy is continually expanding and unifying phenotypes or histotypes have yet to emerge. Recessive TTNopathy is perhaps the most prevalent subtype. Patients typically have diffuse extremity weakness with onset in infancy or early childhood, with a relatively nonprogressive course. Facial muscles are largely spared, and no cases have yet been identified with ophthalmoparesis. There is an increased risk of cardiomyopathy, the extent of which is uncertain and difficult to predict. An additional obstacle to accurately diagnosing a titinopathy is the large number of *TTN* variants of unknown significance (mostly missense variants) and the risk of improperly attributing pathogenicity to polymorphic changes that do not contribute to a patient's underlying disease. Variants require careful clinical correlation; lower extremity muscle MRI may reveal a pattern of selective involvement of the semitendinosus muscle that can aid in the diagnostic clarification of *TTN*-related myopathy.

TTN encodes the giant protein Titin. Titin spans the length of the sarcomere and is thought to act as a molecular spring to provide mechanical support and stability to the myofiber during muscle contraction. Titin likely also participates in signaling processes within the myofiber. At present, there are no clear disease-modifying therapies. One challenge is that the large size of TTN makes it somewhat difficult to model, and its myriad functions make it difficult to elucidate specific impairments associated with *TTN* mutations.

Management

There are currently no approved therapies for any subtype of congenital myopathy. Care is therefore supportive in nature. Key management considerations are related to respiratory care, feeding assistance, and neuromotor support. Most individuals with congenital myopathy will experience respiratory failure, ranging from severe symptomatology present from birth (requiring mechanical ventilation) to nocturnal hypoventilation with onset in the teen or adult years (managed with noninvasive ventilatory strategies). Feeding difficulties are also common, as facial weakness is a relatively specific clinical feature of congenital myopathies and can often result in an inability to chew/swallow food. A feeding tube is required in more than a quarter of cases. In terms of motor function, approximately 25% of patients with congenital myopathy will fail to independently ambulate, and about 10% of those who walk eventually lose the ability to do so. Musculoskeletal problems, including joint contractures and scoliosis, are common and can be progressive, and scoliosis surgery is commonly required.

Outcomes

The majority of patients have relatively nonprogressive disease and are able to live into adulthood. A fraction of patients present with extremely severe neonatal disease, resulting either in death in infancy or during childhood. Disease outcomes in adults with congenital myopathy are poorly defined, although it is likely that there is progressive disability that is currently under appreciated.

148 Seizures and Epilepsies in Neonates and Children

Tristan T. Sands and M. Roberta Cilio

KEY POINTS

1. A child's age affects the risk for seizures and epilepsies; in turn, epileptic activity has the potential to negatively impact neurodevelopment.
2. Seizure and epilepsy incidences are high in neonates; distinguishing epilepsy from acute symptomatic seizures is critical for appropriate management.
3. Febrile seizures affect 2% to 5% of children, most presenting between 6 months and 3 years; only 2% to 5% of children with febrile seizures have epilepsy.
4. Epilepsy syndromes, defined by age of onset, clinical context, seizure type(s), and findings on electroencephalography, have implications for treatment and prognosis.
5. Single gene causes of epilepsy in children are increasingly identified and precision medicine approaches are actively being pursued.
6. Children with refractory epilepsy may be surgical candidates; cortical dysplasia is a common cause of epilepsy leading to neurosurgical intervention.

INTRODUCTION

Incidence of seizures and epilepsy peaks in the first years of life, stabilizes after adolescence, and rises again in old age. A child's age in part determines the risk for seizures and how epilepsy may manifest and, in turn, seizures and epilepsy have the potential to negatively impact neurodevelopment. The age-dependent expression of epilepsy gives rise to particular conditions, each characterized by the age of onset, clinical context, seizure type(s), electroencephalography (EEG) findings, associated etiologies, and prognosis (Fig. 148.1).

The evaluation of unprovoked seizures relies not only on history and examination but also crucially on EEG monitoring for characterization of the brain activity, accurate seizure identification, and clarification of seizure type. This initial workup determines subsequent investigations into etiology, selection of antiseizure medication, and family counseling.

Epilepsy in children may be acquired, following brain injury or associated with cerebral malformations, genetic syndromes (eg, trisomy 21), inborn errors of metabolism, and pathogenic variants in a growing number of genes identified as monogenic causes of neurodevelopmental disability and/or epilepsy. In many cases, the cause of epilepsy remains undetermined, but the number of patients with unknown etiology is progressively decreasing thanks to the advances in EEG monitoring, neuroimaging, and genetics.

FIGURE 148.1 Epilepsy syndromes by age of onset. "Febrile seizures" is italicized as an age-dependent condition not traditionally diagnosed as epilepsy.

AGE-DEPENDENT SEIZURES NOT TRADITIONALLY DIAGNOSED AS EPILEPSY

In the following section, we discuss seizures in neonates because of particularities related to the expression of seizures in the setting of early brain development. We then discuss seizures provoked by fever in the absence of central nervous system (CNS) infection in infants and toddlers, which is one of the most common neurologic complaints in the pediatric emergency department.

Neonatal Seizures

Seizure incidence is high in the neonatal period, affecting 1 to 3.8 per 1,000 term neonates. Most cases are due to acute brain insults, occur in their immediate aftermath, and resolve after the acute period passes. The most common etiologies of seizures in neonates include hypoxic ischemic encephalopathy (38%), ischemic stroke (18%), and intracranial hemorrhage (12%). Not all seizures in neonates are acute symptomatic "neonatal seizures," however, as neonatal-onset epilepsies account for about 13% of newborns with seizures. These neonatal epilepsies (discussed in a subsequent section) must be identified early, as the workup and management are different from that of acute symptomatic seizures.

Long-term polygraphic EEG recording is essential for accurate detection of seizures in neonates, as most of these seizures have no reliable clinical correlate. Conversely, many abnormal behaviors that raise concern for seizures do not have any electrographic correlate and therefore do not need to be treated with antiseizure medications. In general, suspected seizures, unexplained recurrent abnormal paroxysmal events, encephalopathy, or risk for brain injury are all appropriate indications for prolonged EEG monitoring.

Acute symptomatic seizure burden is often high and status epilepticus is common, with or without clinical manifestations. Seizures are often difficult to control and the two treatments with the highest level of evidence, phenobarbital and phenytoin, are effective in less than half of cases LEVEL 1.[1] Guidelines recommended by the American Clinical Neurophysiology Society suggest at least a 24-hour long EEG monitoring after the last recorded seizure. While the optimal duration of treatment is unknown, it is probably safe to discontinue antiseizure medications as early as 72 hours of seizure freedom in neonates with acute symptomatic seizures, and it has become common practice at some centers to stop treatment prior to discharge.

Febrile Seizures

Febrile seizures (FS) are seizures associated with a fever, in the absence of a CNS infection or other acute symptomatic etiology in children without prior unprovoked seizures. Thorough evaluation to exclude these causes is of the utmost importance, and there are published guidelines from the American Academy of Pediatrics that include indications for lumbar puncture LEVEL 1.[2] FS are the most common cause of seizures in the pediatric population, affecting an estimated 2% to 5% of children. Initial FS usually (90%) occur prior to 3 years of age. Peak incidence is between 18 and 24 months and only 6% occur prior to 6 months. The nature of the underlying predisposition to FS in these children is usually unknown, but genetic factors likely play a role, as 25% to 40% of affected children have a positive family history.

About two-thirds of FS occur within the first 24 hours of illness, mainly as the patient's temperature is rising. Indeed, in some children, the seizure is the first indication of illness. FS can be divided into simple and complex types. FS are simple when they are isolated, brief, and generalized clonic or tonic-clonic. Complex FS have focal features or are followed by a postictal focal neurologic deficit (Todd paresis), last more than 15 minutes, or occur more than once within 24 hours. About one-third of children with FS have more than one episode, but greater than three occur in less than 5%. Risk factors for recurrence include age at the time of the first FS (higher if prior to 18 mo and especially if before 12 mo), first-degree relatives with a history of FS, low peak temperature, and a short duration of fever before the seizure (sometimes before recognition). Whether the seizure type is complex or simple is not predictive of recurrence.

Despite risk of recurrence, FS per se do not imply a diagnosis of epilepsy and patients are usually not started on antiseizure medication. Antipyretics, given early in the illness, are recommended for treating the fever, although it is unclear that they reduce the risk of FS. Acute management of prolonged FS demands the same urgency and approach as other prolonged seizures, as they entail risk of long-term sequelae. Indeed, febrile status epilepticus has been shown, in the prospective FEBSTAT study, to lead to acute hippocampal injury, subsequently progressing to mesial temporal sclerosis in some cases. As having had a prolonged FS increases risk of future prolonged FS, such patients should have a rescue medication for use at home

The relative risk of epilepsy is increased by a history of an FS on the order of two to three times that of the general population, but the absolute risk remains low (2%-5%). It is likely that children with very early or late onset and with more than three FS are at higher risk.

AGE-DEPENDENT EPILEPSIES AND EPILEPSY SYNDROMES IN NEONATES AND CHILDREN

Epilepsy syndromes are characterized by age at onset, clinical context, seizure type(s), and findings on EEG. Each is associated with a particular set of etiologies and prognosis. The term *benign* is used in relation to prognosis in a relative sense, as in many ways none of these conditions are truly benign. There is an effort to shift to terminology such as "self-limited" if the seizures remit with time or "pharmacoresponsive" if the seizures respond well to medications, but these features are neither necessary nor sufficient for generally good outcomes and we retain the term. Similarly, the term *idiopathic* is used to describe epilepsy syndromes in which the cause is unknown and there are no aspects suggesting a hidden structural etiology. There has been a tendency to abandon the term, for example, replace idiopathic generalized epilepsy with genetic generalized epilepsy, but this overstates our understanding of the causes of these epilepsies and again we have retained the term *idiopathic*. Finally, some epilepsy syndromes are *epileptic encephalopathies*,

a term defined by the International League Against Epilepsy as a condition in which

> *The epileptic activity itself may contribute to severe cognitive and behavioral impairments, above and beyond what might be expected from the underlying pathology alone (such as a cortical malformation), and that these may worsen over time. Certain syndromes may be referred to as epileptic encephalopathies, but the encephalopathic effects of seizures and epilepsy may potentially occur in association with any form of epilepsy* LEVEL 1.[3]

Benign Epilepsies in Neonates and Infants

Benign epilepsies presenting in the first year of life occur in otherwise well neonates and infants with normal development, neuroimaging and interictal EEG. Genetic investigations for benign epilepsy in infancy should include *KCNQ2*, *KCNQ3*, *SCN2A* and, with onset beyond the neonatal period, *PRRT2*. These benign epilepsies with onset in the first year of life all tend to respond well to carbamazepine (CBZ), regardless of the gene, allowing for early treatment based on clinical presentation.

Benign Familial Neonatal Epilepsy

Benign familial neonatal epilepsy (BFNE) is a dominantly inherited epilepsy caused by pathogenic variants in *KCNQ2* and *KCNQ3* genes, encoding voltage-gated potassium channels responsible for a subthreshold current important in limiting neuronal excitability. Seizures begin in the first few days of life and tend to remit after weeks to months. In between seizures, the exam is normal and the EEG shows only mild abnormalities. Seizures are focal with shifting laterality, characterized by asymmetric tonic posturing often accompanied by apnea, evolving to unilateral or bilateral asynchronous clonic jerking. Seizures last 1 to 2 minutes but may be frequent, as many as 20 to 30 times a day. The seizures are highly responsive to CBZ. Up to 25% of patients develop epilepsy later in life, particularly those who have experienced a higher number of seizures in the neonatal period. Of note, *KCNQ2* and *KCNQ3* can rarely cause infantile epilepsy with onset outside of the neonatal period as well.

Benign Familial Neonatal-Infantile Epilepsy

Benign familial neonatal-infantile epilepsy is a dominantly inherited epilepsy with seizures resembling those of BFNE but with onset from 2 days to 6 months (mean 3 mo). It is associated with pathogenic mutations in the *SCN2A* gene, encoding a voltage-gated sodium channel localized to the axon initial segments, where it plays a role in regulating the generation and propagation of action potentials.

Benign Familial Infantile Epilepsy

Benign familial infantile epilepsy is a dominantly inherited epilepsy with onset of seizures in otherwise healthy infants between 4 and 20 months of age (peak around 6 mo) caused by pathogenic variants in *PRRT2*, which encodes a presynaptic protein implicated in neurotransmitter release. Seizures last 1 to 4 minutes and are focal in onset with initial head and eye deviation followed by uni- or bilateral tonic-clonic activity. Laterality of the initial semiology varies for the same patient, and seizures can occur in clusters. Seizures typically respond to CBZ. The interictal EEG is normal, and the seizures resolve by 2 years. A sporadic form of benign infantile epilepsy occurs that is indistinguishable from BFIE except with respect to family history. Patients with pathogenic *PRRT2* variants may also develop paroxysmal dyskinesia with brief attacks of dystonia or choreoathetosis, referred to as *infantile convulsions with choreoathetosis*.

Epileptic Encephalopathy Syndromes in Neonates and Infants

Age-dependent epileptic encephalopathies are epilepsy syndromes that present at certain developmental stages, each defined by frequent seizures of a particular type, distinctive abnormal EEG findings, and neurodevelopmental impairment. Each age-dependent epileptic encephalopathy syndrome may be caused by a variety of innate and acquired etiologies, a given etiology may present with different syndromes in different patients, and a given individual may transition from one syndrome to another over time, suggesting that each condition represents a common final expression of epileptic brain dysfunction determined by developmental period.

Ohtahara Syndrome and Early Myoclonic Encephalopathy

Two electroclinical syndromes, Ohtahara syndrome (OS) and early myoclonic encephalopathy (EME), represent the earliest of the age-dependent epileptic encephalopathies, with onset in the neonatal period. The syndromes share encephalopathy and a neonatal suppression-burst EEG pattern but differ principally in the main seizure type, either epileptic spasms or multifocal myoclonic seizures. The main seizure type in OS is tonic-spasms, but focal seizures may be seen in one-third of cases. An EEG shows a suppression-burst pattern, invariant in wakefulness and sleep. OS mainly results from structural lesions (eg, large malformations of cortical development [MCDs]) and/or de novo variants in intolerant genes important for brain function. Focal lesions may be betrayed by asymmetry of the EEG or by consistent lateralizing seizure semiology. The condition is often refractory to treatment and associated with high mortality and poor neurodevelopmental outcomes. Subsequent evolution to West syndrome (WS) is common in both OS and EME.

Myoclonic seizures are the main seizure type in EME. They are multifocal, low in amplitude, random in timing and location, and can be present during wakefulness and sleep. Focal seizures, usually subclinical, may also occur. The suppression-burst pattern may be limited to, or most pronounced in sleep and has very long interburst intervals in comparison to OS. EME is associated with high morbidity and mortality. The most important associated etiologies are inborn errors of metabolism, usually autosomal recessive disorders, resulting from variants in genes encoding enzymes or metabolite transporters. The most common reported specific etiology is glycine encephalopathy (previously known as *nonketotic hyperglycinemia*).

Over the last decade, long-term video-EEG monitoring in the nursery, advances in neuroimaging, and metabolic testing together with readily available sophisticated genetic analysis has allowed for the identification of an increasing number of specific etiologies of neonatal epilepsy in newborns diagnosed with OS and EME, including KCNQ2 encephalopathy, SCN2A encephalopathy, glycine encephalopathy, and pyridoxine-dependent epilepsy. Increasingly, labeling neonatal epileptic encephalopathy as OS or EME is less helpful for prognosis and treatment than knowing whether there is a responsible brain malformation and/or identifying the underlying genetic cause.

West Syndrome

WS is an age-dependent infantile epileptic encephalopathy with onset typically at 4 to 7 months of age, characterized by a triad of epileptic spasms, an EEG pattern of chaotic high-voltage slow waves and multifocal spikes termed *hypsarrhythmia* (Fig. 148.2A), and neurodevelopmental regression or stagnation. The initial clinical manifestation of epileptic spasms may be subtle and easily misdiagnosed as episodes of colic or reflux or as startles. A high index of suspicion is important in infants presenting with recurrent stereotyped episodes, most often in clusters, as early treatment is important for outcomes. Clusters of spasms commonly occur during transitions to and from sleep. Ictal EEG shows a diffuse or lateralized slow wave usually associated with an electrodecrement and/or fast activity. As with OS

FIGURE 148.2 Hallmark electroencephalography findings in selected epilepsy syndromes. **A:** Hypsarrhythmia in a drowsy 6-month-old infant with West syndrome and previously normal development prior to successful treatment with adrenocorticotropin hormone. **B:** Centrotemporal spikes *(arrows)* in a 4-year-old boy with childhood epilepsy with centrotemporal spikes. **C:** Typical absence seizure provoked by hyperventilation in an 8-year-old girl with childhood absence epilepsy.

and EME, the etiology of WS is variable and can result from acquired brain injury (eg, hypoxic-ischemic brain injury), pathogenic genetic variants, and/or MCD. Many infants subsequently progress to Lennox-Gastaut syndrome (LGS).

The American Academy of Neurology and Child Neurology Society practice parameter on treatment of WS in 2012 concluded that (1) low-dose adrenocorticotropin hormone (ACTH) should be considered; (2) ACTH or vigabatrin (VGB) may be offered for short-term treatment, with ACTH preferred over VGB unless the cause is tuberous sclerosis complex (TSC); (3) hormonal therapy may be considered for use in preference to VGB in previously normal infants with WS of unknown cause to possibly improve developmental outcome; and that (4) a shorter lag time to treatment with either hormonal therapy or VGB possibly improves long-term developmental outcomes LEVEL 1.[4] For WS in the setting of TSC, level C evidence supports a higher response rate with VGB. Recently, there has been interest in using both hormonal therapy and VGB simultaneously as first-line treatment, based on an open-label study that suggested improved outcomes.

Genetic Developmental and Epileptic Encephalopathies in Neonates and Infants

Many severe genetic epilepsies have developmental consequences arising directly from the effect of the genetic mutation in addition to the effect of the frequent epileptic activity on development. In order to acknowledge that both the developmental and the epileptic component may be playing a role in the clinical presentation, it has been recently suggested to include the word "developmental" to define many genetic epileptic encephalopathy, hence "developmental and epileptic encephalopathy" (DEE) LEVEL 1.[5] In the following text, we review a selection of DEEs. As a rule, each gene is associated with a spectrum of conditions. The list of genes is not exhaustive and continues to grow (**Table 148.1**). We have focused on genes that cause epileptic encephalopathy in the heterozygous or hemizygous state (ie, autosomal dominant or X-linked genes). Of note, there are a number of genetic syndromes resulting from copy number variants that frequently cause epilepsy (eg, Wolf-Hirschhorn syndrome, trisomy 21) that are not discussed.

KCNQ2 Encephalopathy

De novo missense variants in *KCNQ2* cause a neonatal-onset epilepsy with seizures starting in the first days of life, encephalopathy, and a suppression-burst or multifocal epileptiform interictal EEG pattern. Whereas the variants in *KCNQ2* associated with BFNE result in a partial loss of function, variants associated with DEE have more profound consequences on channel function (eg, dominant negative effects). The seizure semiology is the same as that for BFNE and they also respond well to CBZ. Outcome tends to remain poor despite seizure control, arguing for additional developmental roles for *KCNQ2*. Both a common cause of neonatal epileptic encephalopathy (identified in over one-third of cases) and responsible for the majority of benign neonatal epilepsy, *KCNQ2* is arguably the most important epilepsy gene in the nursery.

STXBP1 Encephalopathy

Heterozygous de novo variants in *STXBP1*, encoding a regulator of synaptic exocytosis, cause a spectrum of DEE most commonly with onset in the neonatal or infantile period and epileptic spasms or tonic seizures as main seizure type. Approximately 20% of cases present with OS, and others present with nonsyndromic early-onset epilepsy and developmental encephalopathy (approximately 50%) or WS (approximately 10%).

GNAO1 Encephalopathy

Heterozygous de novo missense variants in the GTP-binding domain of *GNAO1*, encoding the α subunit of a heterotrimeric guanine-binding protein (G-protein), a signaling molecule with a role in calcium current inhibition, are associated with a phenotype characterized by hypotonia, developmental delay and seizures, and/or a hyperkinetic movement disorder with onset in the first 3 months of life. Deep brain stimulation may be helpful in treating the movement disorder in these patients.

ARX Disorders

ARX variants are associated with a spectrum of X-linked conditions ranging from OS, lissencephaly with abnormal genitalia, to intellectual disability with focal dystonia. There is a great deal of pleiotropy within families sharing the same mutation. Expansion in either of two polyalanine tracts in the gene product of *ARX* are an important cause of early-onset DEE and may be missed by next generation sequencing diagnostic approaches.

SCN2A Encephalopathies

De novo variants in *SCN2A* are associated with a staggering variety of phenotypes, ranging from OS, to refractory WS with comorbid hyperkinetic movement disorder, to intellectual disability with autism in patients with or without epilepsy. It has been suggested that early infantile, sodium channel blocker–responsive epilepsy results from gain-of-function missense variants (as with BFNIE), whereas other phenotypes result from loss-of-function or mixed effects on the channel.

CDKL5 Encephalopathy

Pathogenic variants in *CDKL5* cause a unique X-linked condition principally seen in girls (12:1 female to male ratio) that presents in the first 3 months of life. A three-stage electroclinical course has been described with an early period of developmental delay and seizures, followed by epileptic spasms, typically with a "hypermotor-tonic-spasms" seizure sequence and developmental stagnation with or without hypsarrhythmia. Subsequently, patients develop refractory epilepsy with multiple seizure types and high amplitude slowing and bursts of spikes and polyspikes on EEG. Developmentally, only about a third of females with the condition learn to walk and males acquire minimal motor skills.

Epilepsy of Infancy With Migrating Focal Seizures

Epilepsy of infancy with migrating focal seizures (EIMFS) associated with de novo missense variants in *KCNT1*, is a severe electroclinical syndrome that presents within the first 6 months of life with many patients presenting in the neonatal period. Previously well infants suffer developmental deterioration in the setting of medically intractable multifocal seizures that grow increasingly frequent till they become nearly continuous. Other genes have been reported in association with an EIMFS phenotype, but only in EIMFS associated with *KCNT1* variants have the seizures been demonstrated to migrate from one focus to another. Interictal EEG rapidly deteriorates from normal to multifocal epileptiform activity. Developmental impairment is severe to profound and mortality rates are high. The *KCNT1* encodes a sodium-activated potassium channel that mediates slow hyperpolarization that accompanies repetitive neuronal firing. The pathologic mutations

TABLE 148.1 Prominent Monogenic Causes of Epilepsies and Epilepsy-Related Conditions

Gene	Locus	Disorders	Gene Product	Function	Mechanism
AKT3	1q43-q44	MPPH2, HME, FCD type IIb	Protein kinase B gamma	MTOR signaling pathway repressor	LoF
ALDH7A1	5q23.2	Pyridoxine-dependent epilepsy	Antiquitin	α-Aminoadipic semialdehyde dehydrogenase in the pipecolic acid pathway of lysine catabolism	LoF (recessive)
ARX	Xp21.3	X-linked infantile spasms, WS, OS, lissencephaly with abnormal genitalia	Aristaless-related homeobox	Transcriptional regulator critical for cortical interneuronal fate	LoF
CDKL5	Xp22.13	CDKL5 deficiency disorder	Cyclin-dependent kinase-like 5	Serine-threonine kinase; role in transcriptional regulation and neuronal development	LoF
CHD2	15q26.1	MAE	Chromodomain helicase DNA-binding protein 2	Chromatin remodeling with effects on gene expression	LoF
CHRNs (A2, A4, B2)	8p21.2 20q13.33 1q21.3	ADNFLE	Cholinergic receptor; nicotinic α_2, α_4, and β_2 subunits	Nicotinic acetylcholine receptor; excitatory ligand-gated ion channel	GoF
CSTB (EPM1)	21q22.3	Unverricht-Lundborg disease	Cystatin B	Regulator of cathepsins, lysosomal enzymes involved in protein breakdown	LoF (recessive)
DCX	Xq23	Lissencephaly, SBH ("double cortex")	Doublecortin	MAP	LoF
DEPDC5	22q11.2-q11.3	FFEVF, ADNFLE, sporadic focal epilepsy, FCD type IIb	Disheveled, Egl-10 and pleckstrin domain-containing protein 5	Component of GATOR (GAP for Rag GTPases that regulate MTOR activity)	LoF
DNM1	9q34.11	WS	Dynamin-1	GTPase specific to brain with role in presynaptic endocytosis	LoF
EPM2A	6q24.3	Lafora disease	Laforin	Regulation of glycogen formation	LoF (recessive)
FLNA	Xq28	PVNH	Filamin A	Actin-binding protein important in cross-linking and anchoring to the cell membrane	LoF
FOXG1	14q12	WS	Forkhead box g1	Transcriptional repressor implicated in neuronogenesis	GoF/LoF
GLI3	7p14.1	Hypothalamic hamartoma	GLI-Kruppel family member 3	Zinc finger transcription factor that functions in the sonic hedgehog signaling pathway	LoF
GNAO1	16q13	OS	Guanine nucleotide-binding protein, alpha activating activity polypeptide O	G protein–coupled receptor component; regulates calcium current inhibition	LoF
GNAQ	9q21.2	Sturge-Weber syndrome	Guanine nucleotide–binding protein, Q polypeptide	α subunit of a heterotrimeric GTP-binding protein that mediates stimulation of phospholipase C-β during blood vessel development	LoF (somatic only)
GRIN2A	16p13.2	Epilepsy-aphasia spectrum syndromes	Glutamate receptor, ionotropic, NMDA 2A	NMDA α_2 receptor, a ligand-gated ion channel involving in learning and memory	LoF/GoF
KCNQ2	20q13.33	BFNE, sporadic benign neonatal epilepsy, KCNQ2 encephalopathy	Kv7.2	Voltage-gated ion channel; regulates subthreshold potassium currents	LoF
KCNQ3	8q24.22	BFNE	Kv7.3	Voltage-gated ion channel; regulates subthreshold potassium currents	LoF
KCNT1	9q34.3	EIMFS, ADNFLE	Potassium channel, sodium-activated subfamily T, member 1	Sodium-activated potassium ion channel; mediates slow hyperpolarization accompanying repetitive neuronal firing	GoF
LGI1	10q23.33	ADFEAF	Leucine-rich glioma inactivated 1	Interacts with ligand-gated and voltage-gated ion channels in the pre- and postsynaptic membrane	LoF

(table continues on page 1508)

TABLE 148.1 Prominent Monogenic Causes of Epilepsies and Epilepsy-Related Conditions *(continued)*

Gene	Locus	Disorders	Gene Product	Function	Mechanism
MECP2	Xq28	Rett syndrome, MECP2 duplication syndrome	Methyl-CpG binding protein 2	Transcriptional repressor	LoF/GoF
MEF2C	5q14.3	WS	Myocyte enhancer factor 2c	Transcription factor important in synapse elimination during forebrain development	LoF
MT-TK	Mitochondrial	MERRF	Transfer RNA, mitochondrial, lysine	Mitochondrial tRNA for lysine	LoF
MTOR	1p36.22	HME	Mechanistic target of rapamycin	Key kinase in the MTOR signaling pathway	GoF
NBEA	13q13.3	MAE	Neurobeachin	Regulates synaptic structure and function through targeted trafficking of postsynaptic proteins	LoF
PAFAH1B1 (LIS1)	17p13.3	Lissencephaly, SBH	Platelet-activating factor acetylhydrolase, isoform 1B, α subunit	Regulator of the motor protein dynein	LoF
PCDH19	Xq22.1	PCDH19 epilepsy	Protocadherin 19	Cell-cell adhesion and signaling	LoF
PIK3CA	3q26.32	MCAP, HME, FCD type IIb	Phosphatidylinositol 3-kinase catalytic subunit α	MTOR signaling pathway repressor	LoF
POLG	15q26.1	Alpers syndrome	Polymerase, DNA, gamma	Replication of mitochondrial DNA	LoF (recessive)
PRRT2	16p11.2	BFIE, sporadic benign infantile epilepsy, PKD, ICCA	Proline-rich transmembrane protein 2	Regulation of presynaptic neurotransmitter release	LoF
SCN1A	2q24.3	DS, GEFS+	Nav1.1	Voltage-gated sodium channel; regulates excitability of inhibitory cortical interneurons	LoF
SCN2A	2q24.3	BFNIE, SCN2A encephalopathy	Nav1.2	Voltage-gated sodium channel; critical role in regulating neuronal action potential during first several months of life	GoF/LoF
SCN8A	12q13.13	EOEE	Nav1.6	Voltage-gated sodium channel; critical role in regulating neuronal action potential	GoF/LoF
SLC2A1	1p34.2	Glut1 deficiency syndrome	Solute carrier family 2, member 1	Glucose transporter	LoF
SLC6A1	3p25.3	MAE	Solute carrier family 6, member 1	GABA transporter	LoF
STXBP1	9q34.11	OS, WS	Syntaxin-BFNIE-binding protein 1	SM (Sec1p/Munc18) family member; regulates SNARE complexes during exocytosis	LoF
SYNGAP1	6p21.32	EMA, MAE	Synaptic Ras GAP 1	GAP, negative regulator of signaling interactions in the postsynaptic terminal	LoF
TPP1 (CLN2)	11p15.4	NCL type II	Tripeptidyl peptidase I	Lysosomal serine protease involved in breakdown of certain peptides	LoF (recessive)
TSC1, TSC2	9q34.13 16p13.3	TSC	Hamartin; Tuberin	GAP, negative regulator of MTOR signaling	LoF
TUBA1A	12q13.12	Microlissencephaly	Tubulin alpha-1a	Tubulin subunit, component of microtubules	LoF

Abbreviations: ADFEAF, autosomal dominant focal epilepsy with auditory features; ADNFLE, autosomal dominant nocturnal frontal lobe epilepsy; BFIE, benign familial infantile epilepsy; BFNE, benign familial neonatal epilepsy; BFNIE, benign familial neonatal-infantile epilepsy; CDKL5, cyclin-dependent kinase-like 5; DS, Dravet syndrome; EIMFS, epilepsy of infancy with migrating focal seizures; EMA, epilepsy with myoclonic-absences; EOEE, early-onset epileptic encephalopathy; FCD, focal cortical dysplasia; FFEVF, familial focal epilepsy with variable foci; GABA, γ-aminobutyric acid; GAP, GTPase activating protein; GEFS+; genetic epilepsy with febrile seizures plus; GoF; gain of function; HME, hemimegalencephaly; ICCA, infantile convulsions with choreoathetosis; LoF, loss of function; MAE, epilepsy with myoclonic-atonic seizures; MAP, microtubule-associated protein; MCAP, megalencephaly-capillary malformation syndrome; MERRF, myoclonic epilepsy with ragged-red fibers; MPPH2, megalencephaly-polymicrogyria-polydactyly-hydrocephalus syndrome 2; MTOR, mechanistic target of rapamycin; NCL, neuronal ceroid lipofuscinosis; NMDA, *N*-methyl-D-aspartate 2A; OS, Ohtahara syndrome; PKD, paroxysmal kinesigenic dyskinesia; PVNH, periventricular nodular heterotopia; SBH, subcortical band heterotopia; SNARE, soluble NSF-attachment protein receptor; TSC, tuberous sclerosis complex; WS, West syndrome.

increase the current amplitude through increased cooperativity between individual channels. The *KCNT1* can cause a spectrum of epilepsies, including a form of autosomal dominant nocturnal frontal lobe epilepsy. Although quinidine can reverse the increased conductance imparted by some pathologic gain-of-function mutations in vitro, therapeutic trials in patients have been disappointing.

SCN8A Encephalopathy

De novo missense variants in *SCN8A*, encoding a voltage-gated sodium channel causes a spectrum of epilepsies, including an early-onset epileptic encephalopathy, presenting with multiple seizure types during infancy with onset around 4 to 5 months of age. Ataxia or a hyperkinetic movement disorder are common. A high rate of sudden unexpected death in epilepsy has been observed in patients. Similar to *SCN2A*, gain-of-function effects, including impaired channel inactivation or shifted voltage dependence, account for some conditions while loss-of-function variants are responsible for others.

Genetic Epilepsy With Febrile Seizures Plus

Genetic epilepsy with febrile seizures plus (GEFS+) is an autosomal dominant epilepsy syndrome with incomplete penetrance, in which at least two family members have febrile and/or afebrile seizures. Several genes have been implicated, including *SCN1A*.

Dravet Syndrome

Variants in *SCN1A* were originally identified in GEFS+ families, but *SCN1A* was subsequently discovered to be the major gene for Dravet syndrome (DS), accounting for >85% of cases. *SCN1A* encodes a voltage-gated sodium channel important for inhibitory interneuron function. DS has an onset between 3 and 8 months (peak at 6 mo) and presents with bouts of status epilepticus with hemiclonic or generalized clonic or tonic-clonic seizures most often triggered by increased temperature. Typically, even a mild increase in body temperature due to fever, hot weather, or hot bath can be a triggering factor. These episodes become frequent over time and, between 1 and 4 years, other seizure types appear, including myoclonic jerks, atypical absences, and focal impaired awareness seizures. The EEG is usually normal at onset but progresses to generalized, focal, and multifocal abnormalities. Photosensitivity is present early in approximately 40% of patients. The occurrence of sudden unexplained death in epilepsy is relatively high. From the second year of life, children demonstrate variable neurologic impairment, such as ataxia and corticospinal tract dysfunction, as well as behavioral disturbances, and learning disabilities. Seizure frequency tends to stabilize or decrease after 5 years, but developmental outcomes remain severe. CBZ and other sodium channel blocking agents should be avoided as they may worsen seizures. Valproate (VPA) and clobazam are considered first-line antiseizure medications but rarely result in seizure freedom. Stiripentol has demonstrated efficacy as add-on therapy to these agents. Ketogenic diet, a dietary therapy with a high-fat, low carbohydrate diet, can be considered a second-line therapy in DS with a classical ketogenic diet for children under 2 years of age, a modified Atkins diet for children older than 12 years, and either form of the diet for the ages in-between, based on the child's and family's preferences.

Among the new and emerging therapies, a relevant role is played by pharmaceutical-grade cannabidiol (CBD) and fenfluramine (FEN). CBD has shown efficacy in the treatment of seizure in DS in a randomized controlled trial (RCT) LEVEL 1,[6] and it has recently been approved for use by the U.S. Food and Drug Administration. FEN, which was originally developed as an appetite suppressant, has been reported effective in DS in short and long term retrospective and prospective studies. A multicenter RCT with FEN in add-on in DS has been completed and has shown a high rate of responders (70% with more than 50% reduction in convulsive seizure in the FEN group vs 7.5% in the placebo group). The FEN RCT is still unpublished.

PCDH19 Girls Clustering Epilepsy

PCDH19 encodes a protocadherin, involved in cell-cell adhesion. Variants in *PCDH19* cause epilepsy with an unusual X-linked inheritance pattern that spares males in the carrier state. Onset is usually later than DS, between 6 and 36 months with a median age of 10 months. Seizures are triggered or exacerbated by mild/moderate elevations in temperature and often present initially as FS. There is a characteristic "stormy" ictal pattern with clusters of seizures recurring for several days with variable intervening periods of quiescence, lasting months to years. Seizures are most commonly focal with fearful screaming, apnea, or tonic stiffening. The interictal EEG may be normal or show slowing and/or focal or multifocal epileptiform discharges. Cognitive outcome varies from typical to severe intellectual disability. Behavioral or psychiatric disturbances including autism and schizophrenia may become the most clinically problematic symptoms, especially over time, as the seizures tend to become tractable or diminish in adolescence or adulthood.

Toddler-Onset Epilepsy Syndromes

Lennox-Gastaut Syndrome

The term *Lennox-Gastaut syndrome* is often improperly used as a synonym for symptomatic generalized epilepsy, but like other age-dependent epileptic encephalopathies, such as WS, LGS is defined by the presence of specific seizure types and EEG features. The etiology is variable. LGS can occur in the context of acquired brain injury, pathogenic genetic variants, and/or MCD.

Age of onset is between 3 and 5 years of age. The core seizure types include tonic seizures (the hallmark of LGS), especially arising out of sleep, atonic seizures (drop attacks), and atypical absences. The EEG is poorly organized and shows diffuse, usually frontally predominant, slow (2-2.5 Hz) spike and wave during wakefulness and bursts of generalized paroxysmal fast activity during non–rapid eye movement sleep. Ictal EEG of the atypical absences is characterized by a prolonged runs of the slow spike-and-wave complex described earlier. Atonic seizures associated with a generalized spike- or polyspike-wave and tonic seizures manifest with diffuse fast activity (10-20 Hz) accompanying electrodecrement. In patients who evolve to LGS from WS (approximately 20% of LGS), the tonic component and corresponding electrodecrement of epileptic spasms may become progressively prolonged, morphing into tonic seizures over time. Felbamate, lamotrigine (LTG), topiramate, rufinamide, and CBD all have demonstrated efficacy in treating seizures in LGS in randomized controlled studies. VPA, benzodiazepines, and zonisamide are considered also effective based on clinical experience. As in DS, pharmaceutical-grade CBD has shown efficacy in an RTC LEVEL 1,[7] and it has recently been approved by U.S. Food and Drug Administration for use in this syndrome. FEN has also shown to be effective in this syndrome in open-label studies. The results in RTCs are also very promising but still unpublished.

Epilepsy With Myoclonic-Atonic Seizures

Epilepsy with myoclonic-atonic seizures (MAE), or Doose syndrome, is a rare epilepsy syndrome with peak age of onset between 2 and 6 years. The primary seizure types are myoclonic and myoclonic-atonic with a myoclonic jerk preceding a sudden loss of muscle tone. Ictal EEG shows discharges of generalized spikes or polyspike-and-wave complexes with a prominent subsequent slow wave. Patients usually have other generalized seizure types including atypical absences and generalized tonic-clonic seizures (GTCs). Clinically, there is regression associated with the onset of seizures. Outcomes can be good if patients were previously developmentally normal and seizures are controlled. Variants in a number of genes can present with predominantly generalized seizures in infants and toddlers, some with a MAE-like presentation (eg, *CHD2*, *SLC2A1*, *SLC6A1*, *NBEA*), although in these cases, children are typically impaired prior to onset of the epilepsy and seizure control does not alter disability arising from the genetic etiology. VPA is frequently used as first-line, but ketogenic diet and modified Atkins are effective alternative treatments.

Landau-Kleffner Syndrome and Continuous Spikes and Waves During Slow Sleep

The Landau-Kleffner syndrome (LKS) and continuous spikes and waves during slow sleep (CSWS) are epileptic encephalopathies associated with electrical status epilepticus during slow sleep (ESES). The ESES is the term used to describe an extreme form of sleep-activated EEG activity, quantified by spike-wave index, the number of spikes/the number of seconds of non–rapid eye movement sleep. The exact spike-wave index needed to qualify as ESES varies by author but ranges from over 50% to 85%. The hallmark of the associated clinical syndromes is developmental stagnation or regression. LKS manifests affects previously normal children in early childhood with regression in the domain of language, typically starting with a receptive aphasia. CSWS is a condition of more global regression and, in half of cases, there is premorbid delay. Pathogenic variants in *GRIN2A*, encoding the NMDA receptor α_2 subunit, have been reported to account for up to 20% of children with LKS, raising the possibility for novel therapeutic approaches.

Idiopathic Focal Epilepsies of Childhood

The idiopathic focal epilepsies of childhood represent a set of relatively common, age-dependent, self-limited, and pharmacoresponsive epilepsies characterized by focal seizures in typically developing children with relatively good outcome with regard to seizures and development. Diagnosis relies on recognition of seizure semiology and presence of appropriate (and absence of inappropriate) interictal findings in the correct clinical setting (eg, typical development, absence of focal brain lesions).

Childhood Epilepsy With Centrotemporal Spikes

Childhood epilepsy with centrotemporal spikes (CECTS), previously known as *benign rolandic epilepsy*, is one of the most common epilepsy syndromes and usually presents in typically developing school-aged children (peak at 7-10 y) with focal seizures out of sleep referable to primary sensorimotor regions. Hemifacial and/or unilateral oropharyngeal tingling or numbness is followed by hemifacial jerking, drooling, and often speech arrest. Awareness may or may not be impaired. Seizures are typically brief, lasting 1 to 3 minutes and tend to occur shortly after falling asleep or just before awakening but can occur during wakefulness less commonly. Postictal dysarthria is frequent. A Todd paresis may also be observed after prolonged seizures. Secondary generalization occurs in about half of cases. Interictal EEG shows hallmark bilaterally independent spike and wave discharges, maximal in the central and temporal leads (Fig. 148.2B), and forming a characteristic dipole with the frontal regions. Of note, such centrotemporal spikes may be observed in individuals who never develop seizures, especially relatives of those with a history of CECTS. Moreover, epileptiform abnormalities with a similar appearance may occur in other epilepsies (eg, bilateral polymicrogyria). Therefore, magnetic resonance imaging (MRI) is usually performed early in the course as for other focal epilepsies.

Seizures usually remit within 4 years of onset and prior to 16 years of age. There is a spectrum with regard to seizure frequency with 10% to 20% having only one and 10% to 20% having frequent seizures, but the vast majority have several. Some children with CECTS may not require medication. The decision to initiate antiseizure medications ultimately must take into consideration risks and benefits of everyday medication. When treated, the seizures tend to be responsive (eg, to CBZ or levetiracetam).

Panayiotopoulos Syndrome

Panayiotopoulos syndrome starts on average earlier than CECTS (peak 3-6 y) with focal seizures with autonomic semiology, which may be prolonged. The child typically complains of not feeling well, having nausea, looking pale, and retching or vomiting. There is often unilateral eye deviation, which may recur intermittently throughout the seizure. Initially, awareness is preserved, but, over time, it is usually impaired. The seizure may progress to uni- or bilateral tonic-clonic seizures. Seizures are notable for their long duration, up to 1 hour or more, with status epilepticus being common. Interictal EEG is variable but most often shows focal spike and wave discharges that morphologically resemble those of CECTS, usually including occipital location but extraoccipital spikes are common. Patients usually have one to a few seizures before resolution within 1 to 2 years of onset and there is limited evidence for treatment.

Gastaut Syndrome

Gastaut syndrome presents with a peak age of 8 to 9 years with occipital seizures characterized by elementary visual hallucinations commonly followed by eye deviation, motor features, impaired awareness, etc. Other patients have seizures that manifest with ictal blindness. Half of patients have a postictal headache, and the main differential diagnosis is migraine with aura. Seizures are frequent, commonly daily, but resolve in 2 to 4 years.

Idiopathic Generalized Epilepsies of Childhood

The idiopathic generalized epilepsies of childhood represent a set of age-dependent epilepsies with generalized seizure types (eg, GTCs, myoclonic seizures, and typical absence seizures) with characteristic EEG findings in typically developing children. Although strong genetic influences exist, as indicated by twin studies and population studies, they are not determinative (eg, monozygotic twins can be discordant for epilepsy) and the nature of this influence in most cases appears polygenic.

Childhood Absence Epilepsy

Childhood absence epilepsy (CAE) presents in typically developing school-aged children (4-10 y; peak 5-7 y) with absence seizures. It is relatively common, accounting for 10% to 20% of pediatric-onset epilepsy. Absence seizures are brief, lasting under 20 seconds, but frequent, occurring many times per day. They are characterized by an abrupt loss of awareness and cessation of voluntary behavior, during which automatisms or simple motor phenomena may occur, and are associated with a 3 Hz spike-and-wave discharge time-locked with the psychomotor arrest (Fig. 148.2C). The termination of the seizure is similarly abrupt without a postictal period. Absence seizures can be induced by hyperventilation in over three-fourths of cases, helpful in making the initial diagnosis and subsequently determining seizure control. GTCs can rarely occur.

During absence seizures, thalamocortical projections become synchronized through inhibitory input from the reticular thalamus, resulting in rebound bursting via T-type voltage-gated calcium channels. Feedback to the reticular nucleus perpetuates the synchronization. Ethosuximide, which acts primarily at these T-type calcium channels, as well as VPA, are considered first-line antiseizure medications LEVEL 1.[8] VPA is particularly useful in presence of GTCs in addition to absences. LTG also has demonstrated efficacy and is considered second line. In CAE, seizures usually remit by the end of the second decade.

Jeavons Syndrome

Jeavons syndrome or epilepsy with eyelid myoclonia usually starts in early childhood and is characterized by very brief seizures consisting of eyelid myoclonia with or without associated absences triggered by eyelid closure. Electrographically, there is abnormal fast activity and generalized 3 to 6 Hz polyspikes-and-waves with photosensitivity. Usually, there are infrequent GTCs as well. This epilepsy syndrome is often difficult to treat and usually persists throughout life.

Epilepsy with Myoclonic Absences

Epilepsy with myoclonic absences (EMA) is a rare epilepsy syndrome with mean onset at 7 years of age (although onset can occur from early infancy) characterized by seizures lasting up to 1 minute with 3 Hz generalized spike-and-wave like typical absence seizures. During the absence, there are myoclonic jerks of the upper limbs time-locked with the spikes causing progressive elevation of the upper extremities. Typical absences and GTCs may also occur. The prognosis of EMA remains variable. Therapeutic combinations, such as VPA and ethosuximide, or VPA and LTG, are usually effective; however, in a proportion of patients, seizures are resistant to drug treatment. These patients may experience cognitive deterioration and, in some cases, evolution toward a more severe form of epilepsy, including LGS. The more benign cases usually present with myoclonic absences as the only seizure type, whereas patients who experience other seizures, especially GTCs, in association with myoclonic absences may have a less favorable outcome. Pathogenic variants in *SYNGAP1* cause an epilepsy spectrum overlapping EMA with typical onset in the toddler years.

Juvenile myoclonic epilepsy

Juvenile myoclonic epilepsy (JME) is relatively common, accounting for up to 10% of epilepsy. It usually presents during adolescence (peak from 14-15 y) with myoclonic jerks of the upper limbs most abundant in the first half-hour after waking. Amplitude and clinical symmetry vary depending on the patient's activity. The vast majority of patients also have GTCs, which may start with a cluster of myoclonic seizures evolving to clonic then tonic-clonic motor features. Typical absences are less commonly seen and when present are short, infrequent, and not a major aspect of the presentation. An EEG shows generalized polyspike-and-wave discharges and photosensitivity is common. JME is usually pharmacoresponsive but rarely remits with age. VPA is considered first-line therapy, but it should be avoided if possible in reproductive age women given substantial teratogenic risk. Zonisamide seems to be a good alternative.

Juvenile Absence Epilepsy

Juvenile absence epilepsy is less common than CAE or JME and has a mean onset of 10 to 12 years. Typical absence seizures occur with a lower frequency, but the seizures are often longer. Most patients also have GTCs and may even have myoclonic seizures, making the distinction between juvenile absence epilepsy and JME challenging. As with JME, seizures are usually pharmacoresponsive, but continued treatment is often needed to maintain lifelong seizure freedom.

Epilepsy with Generalized Tonic-Clonic Seizures Alone

Epilepsy with generalized tonic-clonic seizures alone may first present in the first, second, or third decade of life with GTCs occurring most often shortly after awakening from sleep and triggered by sleep deprivation.

Rasmussen Encephalitis

Rasmussen encephalitis (RE) is a chronic hemispheric encephalitis that affects previously healthy school-aged children (median age of 6 y) with relentless medically refractory focal seizures. Multiple seizures commonly emerge over time, including *epilepsia partialis continua*, a rare seizure type described by the International League Against Epilepsy as "recurrent focal motor seizures (typically affecting hand and face, although other body parts may be affected) that occur every few seconds or minutes for extended periods (days or years)." RE causes progressive lateralized atrophy of cerebral gray matter, manifesting as progressive enlargement of sulci and ex vacuo expansion of the lateral ventricle as well as progressive functional deficits referable to the affected hemisphere (cognitive, contralateral motor, contralateral visual hemifield). The inflammation in RE is T-cell mediated, but it is unknown whether the inciting antigens are endogenous or some undiscovered pathogen. Hemispherotomy provides seizure control in the majority of cases and, if performed early, may circumvent deleterious effects of uncontrolled epileptic activity on the unaffected hemisphere.

INBORN ERRORS OF METABOLISM CAUSING SEIZURES AND EPILEPSY IN NEONATES AND CHILDREN

Inborn errors of metabolism associated with seizures include sulfite oxidase and molybdenum cofactor deficiencies, glycine encephalopathy, ornithine transcarbamylase deficiency, Menkes syndrome, disorders of glycosylation, creatine deficiency syndromes, biotinidase deficiency, and many others. These conditions

are rare but important to consider given that they are frequently progressive and may entail specific targeted management. In the following text, we review some selected examples.

Pyridoxine-dependent Epilepsy

Pyridoxine-dependent epilepsy is a rare autosomal recessive condition that presents with frequent seizures, mainly myoclonic and clonic, in the first days of life or even in utero. Neonates with pyridoxine-dependent epilepsy usually present with irritability, restlessness, crying, and vomiting preceding the seizures. *ALDH7A1* encodes antiquitin, an enzyme critical for lysine catabolism. Accumulation of the metabolic intermediate, α-aminoadipic semialdehyde, causes the pyridoxine deficiency. If the condition is suspected, intravenous pyridoxine can be administered empirically, ideally under EEG monitoring and in the neonatal intensive care unit. Immediate clinical response (classically accompanied by an episode of apnea) neither confirms nor rules out the diagnosis. Diagnosis is made through detection of α-aminoadipic semialdehyde in the urine and confirmed through genetic testing. Folinic acid-responsive epilepsy is the same condition.

Glut1 Deficiency Syndrome

Glut1 deficiency syndrome is caused by insufficient transport of glucose from the blood to the brain due to heterozygous variants in the glucose transporter encoded by *SLC2A1*. Most patients present in the first months to years of life. Paroxysmal events, including abnormal eye movements and seizures, are the most common presenting symptoms. Other clinical features emerge over time and include deceleration of head growth, spasticity, ataxia, movement disorder, and intellectual disability. Diagnosis is made through identification of hypoglycorrhachia. Seizures are usually generalized, including absences, GTCs, and myoclonic seizures and patients may present with MAE or early-onset (younger than 3 years of age) CAE. Treatment with ketogenic diet is first-line for seizure control and, if the condition is diagnosed and treated early, may improve the neurodevelopmental outcome.

Progressive Myoclonic Epilepsies

Progressive myoclonic epilepsies (PMEs) are a heterogeneous collection of recessive disorders characterized by myoclonic jerks and seizures with progressive neurologic deterioration. Unverricht-Lundborg disease and Lafora disease are PMEs with onset in previously normal children during late childhood and adolescence. The sialidoses and neuronal ceroid lipofuscinoses are groups of neurodegenerative lysosomal storage diseases that cause PME. Recently, intraventricular treatment with cerliponase alfa as enzyme replacement therapy has been approved for neuronal ceroid lipofuscinoses due to *CLN2*. Alpers syndrome presents with seizures, neurodevelopmental regression, and hepatic degeneration due to mitochondrial DNA depletion, most often resulting from variants in *POLG*, which encodes the mitochondrial DNA polymerase-γ. Frequent focal seizures from the occipital lobes and epilepsia partialis continua are characteristic. Myoclonic epilepsy with ragged red fibers is a PME caused by mutation in the gene for mitochondrial tRNA, *MT-TK*, which is encoded by maternally inherited mitochondrial DNA.

EPILEPSIES ASSOCIATED WITH BRAIN MALFORMATIONS

Epilepsy may result from brain lesions acquired at or after birth (eg, hypoxic-ischemic encephalopathy, stroke), malformations (eg, polymicrogyria) due to in utero injury (eg, due to TORCH infections, such as cytomegalovirus or Zika virus, fetal alcohol exposure), or from MCDs caused by variants in particular genes. MCDs may present with epilepsy at any age but often start in the first years of life. MCDs account for about 15% of pediatric epilepsy with onset before 3 years of age, including almost 40% of cases of neonatal-onset epilepsy. Moreover, MCDs, and particularly focal cortical dysplasias (FCD), represent the most common cause of medically intractable epilepsy leading to epilepsy surgery in the pediatric population.

MCDs reflect the result of abnormal developmental processes during corticogenesis, including cell proliferation, migration, and differentiation. They are generally the result of constitutional or somatic genetic mutations, which arise during development and affect a variable portion of the CNS. Somatic variants in the same gene may cause lesions of different sizes depending on the extent of the affected tissue. As only the affected tissue harbors the mutation, somatic variants may not be detectable in blood. Genes mutated in MCDs encode cytoskeletal-associated proteins and members of the mechanistic target of rapamycin (MTOR) growth signaling pathway.

Cortical Dysgenesis

Cortical dysplasia, ranging in extent from FCD to dysplastic megalencephaly (DMEG) affecting the entire brain, is often the result of pathogenic variants in components of the MTOR pathway. Patients with regions of dysplastic cortex may begin having focal seizures at any age, but onset in the first few years of life is common and there is a risk for developing age-dependent epileptic encephalopathies with the associated seizure types (eg, WS with epileptic spasms in patients with TSC). Identification of the responsible pathway has led to interest in repurposing MTOR inhibitors for epilepsy associated with these "MTORopathies" and a benefit has been demonstrated in a randomized trial of in patients with TSC LEVEL 1.[9]

Focal Cortical Dysplasia

Focal cortical dysplasia is characterized by the presence of an abnormal arrangement of cortical neurons with (type II) or without (type I) the presence of abnormal cellular features, such as dysmorphic neurons with (type IIb), or without (type IIa), balloon cells. Type II FCD (eg, resulting from dominantly inherited or de novo mutation of *DEPDC5*) may reveal itself on MRI as a blurring of the gray-white junction, and/or as T2 hyperintensity, which may extend through the subcortical white matter to the lateral ventricle ("transmantle sign"), be limited to the bottom of a sulcus ("bottom of sulcus sign"), or may appear similar to cortical tubers (see subsequent section). In early infancy, these signal changes on MRI are very different (eg, T1 hyperintensity). Subsequently, between 12 and 30 months, the sensitivity of detection on MRI becomes poor due to incomplete myelination. Given that FCD is a relatively common cause of focal epilepsy with onset in toddlers, that the rate of medical intractability is high with additional risk for epileptic encephalopathy, and that these patients have high rates of seizure freedom following epilepsy surgery, a high degree of suspicion for FCD is warranted in this population even if a lesion cannot be detected on initial MRI.

Tuberous Sclerosis Complex

Tuberous sclerosis complex is a multisystem disorder (brain, skin, lung, kidney, and heart) caused by dominantly inherited pathogenic variants in *TSC1* or *TSC2*. TSC has a great deal of phenotypic variability, as the associated lesions are considered to arise from somatic "second-hits." CNS manifestations include epilepsy, autism, intellectual disability, and dysregulated behavior and sleep. Obstructive hydrocephalus may result from growth of subependymal giant-cell astrocytomas. Epilepsy affects over 90% of individuals and is associated with cortical tubers, regions of cortical dysplasia manifesting as thickened, T2 hyperintense, cortical gyri. Histologically, tubers have dysmorphic neurons and balloon cells like FCD type IIb. VBG is the drug of choice. However, patients with TSC may be excellent surgical candidates if a tuber responsible for the epileptic focus can be identified.

Hemimegalencephaly and Dysplastic Megalencephaly

Hemimegalencephaly (HME) and dysplastic megalencephaly (DMEG) affect one and both cerebral hemispheres, respectively. HME and DMEG exist on a spectrum of lesion size with small FCD type II, sharing histopathology and genetic alteration affecting the MTOR pathway (eg, *PIK3CA*, *AKT3*, *MTOR*). Affected cortex often shows abnormal gyral patterns, and macrocephaly from brain enlargement is common. HME and DMEG may affect the CNS in isolation or occur as part of more general overgrowth syndromes. For HME as for FCD, surgical disconnection (ie, hemispherotomy) is indicated for intractable epilepsy.

Periventricular Nodular Heterotopias

Periventricular nodular heterotopias are abnormal nodular collections of gray matter adjacent to the lateral ventricles, thought to arise during development, as a result of disrupted neuroepithelium. Therefore, they can occur in association with other cerebral malformations, which determine the extent of associated neurodevelopmental disability. Pathogenic variants in *FLNA*, which encodes a protein with a role in cross-linking and anchoring actin filaments to the cell membrane, are a cause of familial periventricular nodular heterotopia with an X-linked recessive mode of inheritance. Seizures may be generated by the heterotopia itself and/or overlying cortex and are often amenable to surgical management.

Lissencephaly

Lissencephaly, "smooth brain," refers to an absent (agyria) or reduced (pachygria) cerebral convolutions. The malformation reflects arrest of neuronal migration after the first trimester. The cortical neurons are actually in a heterotopic collection deep to their appropriate location. Indeed, pathogenic variants in *DCX* on the X chromosome cause lissencephaly in males but cause a subcortical band heterotopia (ie, a "double cortex") in females, for whom lyonization results in two populations of neurons. Pathogenic variants in certain cytoskeletal elements are responsible for lissencephaly, and somatic mutation of these same genes can cause subcortical band heterotopia. Pathogenic variants in *LIS1*, encoding a dynein regulator, cause a posterior predominant lissencephaly, whereas mutation of *DCX*, encoding a microtubule-associated protein, causes an anterior predominant lissencephaly. *TUBA1A* variants can cause microcephaly with lissencephaly and hypoplasia of the cerebellum and white matter tracts (eg, anterior limb of the internal capsule, corpus callosum). Severe to profound intellectual disability is typical in patients with lissencephaly. Seizures usually start in the first months of life and evolution to age-dependent epileptic encephalopathies (eg, WS) is common.

Hypothalamic Hamartomas

Hypothalamic hamartomas (HH) are dysplastic malformations of the hypothalamus that cause epilepsy typically with onset in the first year of life with characteristic gelastic (laughing) seizures and/or dacrystic (crying) seizures. Over time, patients develop other seizure types often with evolution to epileptic encephalopathy. Intellectual disability and severe behavioral dysregulation are common features. Patients may develop central precocious puberty, which can occur independently of epilepsy. Seizures are typically medically refractory and surgical management is the treatment of choice with the goal of disconnecting the HH from the mamillothalamic tracts. Somatic variants of the sonic hedgehog signaling pathway (eg, *GLI3*) have been implicated in the pathogenesis of HH.

Sturge-Weber Syndrome

Sturge-Weber syndrome (SWS) is a neurocutaneous syndrome characterized by angiomatosis of leptomeninges and/or choroid of the eye, usually accompanied by a facial *nevus flammeus* (port-wine stain). Leptomeningeal angiomas cause impaired venous drainage leading to chronic ischemic injury to the adjacent cerebral cortex with associated atrophy and calcifications (tram-track sign). The SWS is caused by somatic variants in *GNAQ*, a signaling molecule important in blood vessel development. The SWS is usually characterized by focal epilepsy, with prolonged focal seizure, with or without secondary generalization, often severe and refractory, leading to epileptic encephalopathy. Patients may develop intellectual disability, hemianopia and progressive hemiparesis, manifesting as a Todd paresis of increasing duration over time, correlated with frequent seizures and recurrent episodes of status epilepticus. Therefore, in refractory patients, resective surgery or hemispherotomy should be considered early.

Pediatric Stroke 149

Sally M. Sultan and Robert H. Fryer

KEY POINTS

1. The highest incidence of stroke in childhood occurs in the neonatal period.
2. Arteriopathies, both transient and progressive, are the most common cause of stroke in childhood.
3. In both neonatal stroke and cerebral venous thrombosis, evaluation for clotting disorders are a key part of the workup.
4. Moyamoya disease/syndrome is a progressive vasculopathy with collateral blood vessel formation that occurs by itself or as part of an underlying genetic disorder.
5. The role of patent foramen ovale closure in childhood stroke remains uncertain.
6. Strokes are common in sickle cell anemia and can be prevented by transfusion (and hydroxyurea).

INTRODUCTION

Stroke incidence peaks at the extreme ends of the age continuum, in both the newborn period and in the elderly, forming a U-shaped curve over the lifespan. After an initial spike in the first week of life, the stroke incidence precipitously drops in childhood and remains low throughout adolescence. There is a steady rise in stroke incidence throughout adulthood, reaching its highest levels in the elderly. Arterial ischemic stroke (AIS) is the most common cause of stroke in the pediatric population, followed by cerebral sinovenous thrombosis (CSVT) and intracranial hemorrhage (ICH). This chapter starts with a discussion of perinatal stroke (<29 d old) followed by stroke in infants, children, and adolescents (29 d old to <18 y of age). Sickle cell anemia (SCA), which carries a very high risk of stroke in childhood and adolescence, is also discussed. The last part of this chapter addresses the growing role of genetics in pediatric stroke disorders.

PERINATAL STROKE

Perinatal stroke is defined as signs and symptoms referable to a vascular event with radiologic or pathologic confirmation of the vascular event. Perinatal stroke most often affects term infants, but it includes strokes that occur from 20 weeks of gestation through 28 postnatal days and can affect preterm infants. A *presumed perinatal stroke* is diagnosed in an older child when neuroimaging shows a chronic stroke with or without delayed focal neurologic signs referable to the vascular lesion. One relatively common presentation of presumed perinatal stroke is the appearance of hemiparesis or early hand preference in an infant between 4 and 8 months of age with imaging showing a chronic infarct.

Epidemiology

Perinatal Arterial Ischemic Stroke

Assessment of data regarding the incidence of neonatal stroke is confounded by difficulties including those patients whose stroke is not identified in the days or weeks after birth. In the National Hospital Discharge Survey (1980-1998), the rate of neonatal ischemic stroke was 17.8/100,000 and hemorrhagic stroke was 6.7/100,000. The overall incidence of neonatal stroke was 26.4/100,000 or 1/4,000 live births per year. This high incidence does not account for infants who present after the first few days of life, children who are diagnosed with a presumed perinatal stroke, and undiagnosed hemiplegic cerebral palsy. Other studies that have attempted to capture strokes identified in the neonatal period along with presumed perinatal stroke and perinatal intracerebral hemorrhage suggest an incidence as high as 1 in 2,200 live births.

The incidence of stroke during the newborn period is at least 10-fold higher than the incidence of stroke in childhood. Some studies have shown a higher rate of perinatal stroke in males than females.

Perinatal Cerebral Sinovenous Thrombosis

The incidence of CSVT in neonates is approximately 2 to 3 per 100,000. CSVT typically occurs in term or near-term infants. In one study, the mean gestational age was 37 weeks, and 19% of the neonates were preterm. The mean birth weight was 2,720 g.

Perinatal Intracranial Hemorrhage

A study of population prevalence of perinatal ICH in Northern California identified approximately 6.2 cases per 100,000 live births for an incidence of approximately 1 in 6,300 live births.

Pathobiology

Perinatal Arterial Ischemic Stroke

The majority of perinatal strokes likely occur in the few days before and after delivery. AIS is most common in the anterior circulation and on the left, specifically involving the middle cerebral artery (MCA). This preference for the left MCA is presumably due to the more direct course of blood flow from the heart and aorta into the left common carotid artery. Approximately one-quarter of perinatal AIS involves both cerebral hemispheres. Despite a recent expansion of research in this field, there are no strong predictors of perinatal stroke. Placental factors, including thrombi formation and inflammation, combined with the presence of transitory right to left circulatory shunts in the newborn circulatory system may contribute to the high incidence of stroke in the perinatal period.

Peripartum Factors

Risk factors for perinatal stroke are incompletely understood but can be divided into those present before the onset of labor

TABLE 149.1 Risk Factors for Perinatal Stroke

Before Labor and Delivery
Primiparity
Preeclampsia
Oligohydramnios
History of infertility
During and After Labor and Delivery
Fetal heart rate abnormality
Emergency caesarean delivery
Chorioamnionitis
Prolonged rupture of membranes
Prolonged second stage of labor
Vacuum extraction
Cord abnormality
Sepsis and meningitis

and those present during or shortly after labor and delivery (Table 149.1). The risk of stroke increases dramatically with each additional risk factor present.

Prothrombotic Factors

The role of prothrombotic factors in perinatal stroke remains unclear. A large meta-analysis that included many observational studies showed a possible association between thrombophilic states and perinatal stroke, but a more recent prospective case-control study showed at best a minimal association between inherited thrombophilic states and perinatal stroke. Furthermore, the levels of many coagulation and anticoagulation factors in the newborn are much lower than in the adult, and laboratory measurements are less reliable.

Infection

Sepsis and meningitis have long been associated with large-artery ischemic strokes and CSVT. In an international series of neonates, 23% had a systemic illness around the time of stroke.

Congenital Heart Disease

Intracardiac thrombi due to congenital heart disease are a source of embolic stroke in the newborn. Approximately one-fifth of neonates have a cardiac risk factor most often in the form of congenital heart disease. Aside from inherited heart disease, there is limited data on other cardiac causes of perinatal stroke. In two series of neonates without known congenital heart disease, echocardiography was not informative.

Perinatal Cerebral Sinovenous Thrombosis

The cerebral sinuses may be subject to injury during the birth process and, as seen in perinatal AIS, inflammation of the placenta may lead to a prothrombotic state. The deep venous system is more prone to thrombosis in the neonatal period compared with childhood. In one study, the involvement of the straight sinus, the vein of Galen, or internal cerebral veins was seen in more than two-thirds of neonates with CSVT.

In neonates with CSVT, concurrent hemorrhagic infarcts are seen in 35% to 50%. Intraventricular hemorrhage (IVH) is found in 19% to 38% of neonates. Concurrent AIS has been reported in 10% and subarachnoid hemorrhage (SAH) in 5%.

Perinatal Intracranial Hemorrhage

In most cases of perinatal ICH, a cause cannot be identified. Occasional cases may be due to hemorrhagic conversion of an arterial or venous infarct. Hemorrhagic disease of the newborn, due to low vitamin K, along with other acquired or congenital coagulopathies are important causes of perinatal ICH.

Clinical Features

Perinatal Arterial Ischemic Stroke

Neonatal seizures are the most common presenting sign of a stroke. In one international series on ischemic stroke, 72% of neonates presented with seizures. Other common presenting signs are changes in tone and level of consciousness. Those that do not present in the perinatal period with seizure come to clinical attention later in life due to focal neurologic deficits or seizures, and a chronic infarct is found on imaging.

Perinatal Cerebral Sinovenous Thrombosis

Neonates are more likely to present with seizures and generalized encephalopathy compared with children with CSVT. Typical neonatal diffuse signs are a depressed level of consciousness, jitteriness, irritability, apnea, poor feeding, and low tone.

Perinatal Intracranial Hemorrhage

More than 50% of neonates with ICH also present with seizures. Neonates are more likely than children to present with signs of encephalopathy such as lethargy, hypotonia, feeding difficulties, and apnea.

Diagnosis and Imaging

Perinatal Arterial Ischemic Stroke

Ultrasound is safe, widely available, and does not require transport of the neonate to an imaging suite. It is sensitive for intraventricular and periventricular blood and chronic infarction, but sensitivity is low for AIS. In one study, only 30% of perinatal AIS was detected on ultrasound. Computed tomography (CT) scan is often avoided in the neonate because of the availability of ultrasound and to prevent exposure to radiation, but where indicated, CT will accurately show superficial ischemic and hemorrhagic lesions. Magnetic resonance imaging (MRI) is safe, more sensitive for early ischemic strokes and superficial lesions, and can often be done without anesthesia in newborns.

Perinatal Cerebral Sinovenous Thrombosis

Symptoms may begin around the time of birth, but diagnosis may be delayed. In one study, the mean age at diagnosis was 9 days of age. Doppler ultrasound is portable and well tolerated, but in one neonatal study, only 48% of CSVT was detected.

Perinatal Intracranial Hemorrhage

Ultrasound is useful in identifying hemorrhage in the neonatal brain; however, it is not as useful in identifying the etiology of the hemorrhage. Magnetic resonance angiography (MRA) can typically show large vascular malformations but may miss small malformations. Conventional angiography can be used to identify smaller malformations.

Management

Perinatal Arterial Ischemic Stroke

Where there is no cardiac indication for aspirin or anticoagulation, there is a recommendation against its use after a first perinatal AIS. For recurrent AIS, aspirin or anticoagulation is suggested. After a stroke, if there is delayed acquisition of milestones, hypotonia, spasticity, or focal deficits, it is reasonable to institute multispecialty therapy. If an *MTHFR* mutation with elevated homocysteine levels is discovered, it is reasonable to give folate and B vitamins to normalize homocysteine levels for secondary stroke prevention. Anticoagulation with low molecular weight heparin (LMWH) and unfractionated heparin (UFH) can be considered in selected neonates with severe thrombophilic disorders and multiple cerebral or systemic emboli. Thrombolytic agents are not recommended in neonates until more information about safety and effectiveness is known.

Perinatal Cerebral Sinovenous Thrombosis

In the large single-center retrospective analysis, 25% of the neonates with CSVT were anticoagulated only after thrombus propagation. Within 2 weeks of diagnosis, thrombus propagation occurred in 4% of treated neonates and 28% of untreated neonates. Propagation was asymptomatic but was associated with new venous infarcts in 10%. Anticoagulant-related ICH occurred in 8% and only happened when there was pretreatment ICH.

Anticoagulation can be considered in neonates with clinical or radiologic evidence of propagating CSVT despite supportive therapy. There is insufficient evidence to recommend the initial routine use of anticoagulation in neonates with CSVT. Despite this recommendation, at many stroke centers, anticoagulation is started with an initial CSVT diagnosis unless there is a significant hemorrhage.

Perinatal Intracranial Hemorrhage

Neonates with ICH resulting from coagulation factor deficiency require replacement of the deficient coagulation factors. Neonates born to mothers exposed to warfarin, phenytoin, or barbiturates may require higher doses of vitamin K. Supportive measures such as treatment of dehydration and anemia should be considered.

Outcome

Perinatal Arterial Ischemic Stroke

Neurologic Deficits

Perinatal stroke is presumed to be the most common cause of hemiplegic cerebral palsy. Initial imaging can be used to predict neurodevelopmental outcomes in perinatal AIS. Strokes that involved the main branch of the MCA, where the entire MCA territory is infarcted, have a poor outcome, with 100% developing hemiplegic cerebral palsy in one study. Other predictors of poor outcome include involvement of the basal ganglia, thalamus, and the middle third of the cerebral peduncle. However, newborns whose strokes do not involve the basal ganglia, thalamus, and cerebral peduncle fare much better, with about 43% to 71% or greater having a normal neurodevelopmental outcome (Fig. 149.1).

Cognitive and Behavioral Deficits

Involvement of the basal ganglia and thalamus is a predictor of cognitive deficits and behavior problems. However, in most other types of unilateral infarction, IQ is generally preserved. Despite the predominance of left-sided MCA infarcts in perinatal AIS, many children will have intact language acquisition.

Seizures and Epilepsy

Although seizures are common in the acute setting of a perinatal AIS, a smaller percentage of patients will go on to develop

FIGURE 149.1 Perinatal arterial ischemic stroke. **A:** Diffusion-weighted imaging image showing a left-sided cortical infarct in a term newborn presenting on the second day of life with seizures. This infant was last seen at 32 months of age off of antiseizure medications and with normal development. **B:** Head computed tomography showing a large right middle cerebral artery/anterior cerebral artery infarct in an infant with hypoplastic left heart syndrome, postoperative from a Fontan procedure, with numerous deep venous thromboses. This infant has a poor prognosis.

epilepsy. One study found that 47% of survivors of perinatal AIS had epilepsy, but other studies have shown a lower rate. Large infarct size seems to be a risk factor for the development of epilepsy after a perinatal AIS.

Recurrence

Recurrent stroke is extremely rare in perinatal stroke except in those newborns with congenital heart disease. In northern California, the 5-year cumulative recurrence rate was only 1.2%. However, newborns with perinatal stroke and cardiac disease have a higher recurrence rate.

Perinatal Cerebral Sinovenous Thrombosis

Anticoagulation for CSVT may be safe even in neonates. In the large single-center review, there were no deaths related to anticoagulation in neonates. Recurrence is seen in 8% of neonates. Recanalization may be better in neonates than in older children. In one study at 3 months, 85% of neonates had complete recanalization.

Outcome is more likely to be normal in neonates without parenchymal involvement due to CSVT. In neonates with infarction, the outcome was normal in only 41% to 43%, and 29% had severe disability at follow-up. The risk of an unfavorable outcome was similar even among neonates with major anticoagulant-related hemorrhage.

Poor outcome includes epilepsy (38% in one series), spastic hemiplegia or tetraplegia, and intellectual disability or developmental delay. A predictor of poor neonatal outcome was the absence of anticoagulant treatment.

Perinatal Intracranial Hemorrhage

Epilepsy occurs in a small proportion of patients with perinatal ICH. Elevated intracranial pressure that requires intervention is a risk factor for the development of epilepsy in patients with perinatal ICH.

Epidemiology

Childhood Arterial Ischemic Stroke

The annual incidence for childhood AIS is 1 to 2 per 100,000 children and peaks among school-aged children. From the first 676 patients in the International Pediatric Stroke Study registry, the largest registry of all pediatric stroke, the median age at first AIS presentation was 5.7 years.

For all childhood stroke, there is a predominance of affected males with an estimated ratio of 3:2 boys:girls. In the California discharge database, the relative risk (RR) for ischemic and hemorrhagic stroke was higher among boys than girls: for AIS, RR 1.25; SAH, RR 1.24; and ICH, RR 1.34. Mortality after AIS was also higher among boys (17% vs 12%).

Studies in the United States have identified racial and ethnic disparities in childhood stroke where black children are at higher risk for ischemic and hemorrhagic stroke than white children. Pediatric stroke mortality was found to be higher in stroke belt states (southeastern United States), compared with other US states.

Childhood Cerebral Sinovenous Thrombosis

Population-based incidence studies report that less than 1 per 100,000 children per year are diagnosed with CSVT (see Chapter 41). Many stroke providers believe true incidence is significantly higher and diagnoses are missed. Among patients with a presumed diagnosis of idiopathic intracranial hypertension, routine imaging discloses CSVT in as many as 26%. CSVT also peaks in school-aged children. The mean age of children at the time of diagnosis is 5 to 9 years.

Childhood Intracranial Hemorrhage

Hemorrhagic stroke can be further broken down into intracerebral hemorrhage, IVH, and SAH. In children, approximately half of all strokes are hemorrhagic. The annual incidence rate ranges from 0.63 to 5.11 per 100,000 children without SCA. ICH affects school-aged children. The median age of affected children is 7 to 10 years. Arteriovenous malformations (AVMs) are the most common cause of ICH in childhood and approximately 10% of nontraumatic childhood ICH remain idiopathic.

Pathobiology

Childhood Arterial Ischemic Stroke

Arteriopathy (50% of Arterial Ischemic Stroke)

Arteriopathy in pediatric stroke is presumed to be nonatheromatous and instead due to inflammation, infection, and inherited disorders of tissue stability and repair. Arteriopathy is found in approximately 50% of childhood AIS, and discrete radiographic and clinical subtypes have begun to be described. Two reported predictors of arteriopathy are a recent upper respiratory infection and SCA. The traditional nomenclature for AIS arteriopathy subtypes are *focal cerebral arteriopathy, moyamoya, intracranial and extracranial arterial dissection, vasculitis, sickle cell arteriopathy, postvaricella arteriopathy*, and other unspecified forms of arteriopathy. Frequencies of arteriopathy subtypes are as reported in the International Pediatric Stroke Study registry.

Focal Cerebral Arteriopathy (25%)

This entity is typically characterized by unilateral mainstem arterial disease with lenticulostriate infarction. An East Asian study found that FCA was reversible in 68%, progressive in 20%, and stable in 12%. Of the patients with reversible arteriopathy, 53% had early worsening. In European cohorts, the course of unilateral arteriopathy was progressive in only 6%, stabilized in 32%, improved in 45%, and completely normalized in 23%. Among patients with a nonprogressive arteriopathy, 44% had an antecedent varicella infection, and 18% had a recurrent stroke or transient ischemic attack (TIA).

Moyamoya (22%)

Moyamoya arteriopathy (see also Chapter 44) is the progressive development of bilateral occlusive disease of the terminal internal carotid arteries (ICAs) with basal collaterals (Fig. 149.2). There may also be involvement of the mainstem branches of the terminal ICA. The term *moyamoya syndrome* is used when there is an accompanying condition (Table 149.2) known to be associated with moyamoya arteriopathy and the term *moyamoya disease* when the disorder is idiopathic. Moyamoya disease is more common in Asian populations, and about half of Asian patients with moyamoya have a mutation in the gene RNF213. Moyamoya arteriopathy is commonly progressive. In a single-center series, progression developed in 45% over 5 years. Stroke recurrence is also high from 20% over 4 years to 38% over 10 years.

FIGURE 149.2 Moyamoya syndrome in a 7-year-old boy with sickle cell anemia who had a seizure and a stroke. **A:** Magnetic resonance angiography of the anterior circulation showing occlusion of bilateral A1 segments and narrowing of both the left *(arrows)* and right terminal internal carotid arteries (ICAs) and middle cerebral arteries. **B:** In the same patient, cerebral angiogram of the left ICA injection showing narrowing of the terminal ICA *(arrow)* extending into middle cerebral artery, along with the fine moyamoya collateral vessels that form at the base of the brain *(arrowheads)*. This child had a bilateral encephaloduroarteriosynangiosis procedure and has done well with no further strokes or seizures.

Craniocervical Arterial Dissection (20% of Arteriopathy)

Arterial dissection in childhood includes intracranial and extracranial dissections. In a meta-analysis of arterial dissection in children younger than 18 years, males were affected considerably more than females: 74% male in anterior circulation dissections and 87% male in posterior circulation dissections. This predominance persisted even for nontraumatic dissections. Of dissection involving the anterior circulation, 40% were extracranial and of dissections involving the posterior circulation, 79% were extracranial. One-third of dissections are spontaneous, but less than a fifth are associated with significant trauma. The mean age of presentation is older than all AIS at 8 to 10 years. Common presenting symptoms are hemiparesis and headache. Neck pain was less common in children. Follow-up after an average of 5 years showed moderate or severe deficits in 14%, recurrent strokes in 9%, and recurrent dissections only after anterior circulation dissection and in 10% of those patients.

TABLE 149.2 Diseases Associated With Moyamoya Syndrome

Autosomal Dominant Inheritance
Neurofibromatosis type I
Alagille syndrome
Noonan syndrome
Costello syndrome
Autosomal Recessive Inheritance
Sickle cell anemia
GUCY1A3 mutation
SAMHD1 mutation
Microcephalic osteodysplastic primordial dwarfism
Seckel syndrome
Recessive X-linked Inheritance
BRCC3/MTCP1 deletion
Aneuploidy Disorder
Down syndrome
Turner syndrome
Other
PHACE syndrome

Vasculitis (12% of Arteriopathy)

Cerebral vasculitis is rare and can be difficult to diagnose in children (see Chapter 43). Vasculitis due to systemic inflammatory conditions, viral, fungal, mycobacterial, and even parasitic infections is more likely than primary central nervous system angiitis. Consider vasculitis where there are infarcts in multiple vascular territories with microhemorrhages.

Sickle Cell Arteriopathy (8% of Arteriopathy)

See later detailed discussion of sickle-cell arteriopathy.

Post–varicella Angiopathy (7% of Arteriopathy)

This entity traditionally results in stenosis of the distal internal carotid and mainstem branches with lenticulostriate infarction. (See later discussion on "Risk Factors, Infection.")

Cardiogenic (30% of Arterial Ischemic Stroke)

Cardiogenic causes of stroke include congenital heart disease, valvular heart disease, arrhythmias, cardiomyopathy, cardiac surgery and catheterization, extracorporeal membrane oxygenation, left ventricular assist device, and Kawasaki disease.

Congenital heart disease is the most common cardiac risk factor, reported in 59% of those with a cardiogenic stroke.

An isolated patent foramen ovale (PFO) was reported in 15% and cardiac catheterization in 8%.

Thromboembolic (15% of Arterial Ischemic Stroke)

Thromboembolic stroke may be due to an indwelling catheter, infection, or a hypercoagulable state that is inherited or acquired.

Cryptogenic Stroke (5% of Arterial Ischemic Stroke)

Cryptogenic stroke, where the etiology of the stroke is unknown despite a comprehensive workup, is reported in approximately one-fifth of children.

Childhood Cerebral Sinovenous Thrombosis

The cerebral veins and sinuses are thin-walled and without valves. Cerebral veins drain into the sinuses that form from dural pockets around the brain. Unlike arterial vascular territories, thrombosis of particular veins does not present with well-defined clinical syndromes. The venous system has considerable anatomic variability, flow can be reversed, and there may be collateral drainage pathways such as through occipital sinuses.

The cerebral veins and sinuses are positioned for thrombotic complications. Venous drainage is slow; it follows a tortuous route and the walls easily distend. A combination of local inflammation in the vessel wall, systemic thrombophilia, hyperosmolality, reduced blood flow, and injury to the vessel wall all work to tip the balance toward cerebral thrombosis. When a thrombus obstructs venous outflow, the pressure becomes high in the venous system. Edema and hemorrhage can develop from high pressure in the capillaries with plasma and red blood cell diapedesis or frank rupture, and the high pressure can exceed arterial perfusion pressure resulting in ischemic infarction. Hydrocephalus with intracranial hypertension will occur when cerebrospinal fluid reabsorption through arachnoid villi and pacchionian body granulations in the dural sinuses becomes impaired. A large thrombus in the superior sagittal sinus, the sinus where most of the reabsorption occurs, will generally lead to a communicating hydrocephalus.

In children, the superior sagittal and lateral sinuses are most often affected, and two or more sinuses or veins are involved. Sinus occlusion may present with intracranial hypertension, whereas an isolated cerebral vein thrombosis may present with focal neurologic signs.

CSVT is a complication of many chronic inflammatory, infectious, and prothrombotic states (Table 149.3).

Prothrombotic tendencies may be present in half of children tested, and more than one abnormality is not uncommon. The meta-analysis of prothrombotic traits in childhood stroke also found a positive association for all of the thrombophilia traits studied with CSVT: antithrombin deficiency, protein C deficiency, protein S deficiency, factor V G1691A mutation, and prothrombin G20210A mutation. An antithrombin deficiency was 18-fold higher in children with CSVT compared to a control population and protein C or S were 6 and 5 times higher in a cohort of children with CSVT.

Childhood Intracranial Hemorrhage

ICH in children is most often intraparenchymal hemorrhage or intraparenchymal hemorrhage with IVH extension. Isolated IVH is rare. Hematoma expansion may occur in one-third of children, and the expansion may be significant, requiring urgent evacuation.

Causes of ICH from three pediatric tertiary care centers in the United States are AVMs (37%), unknown (17%), cavernous malformations (13%), coagulopathy (11%), anticoagulation (9%), aneurysm (9%), developmental venous anomaly (2%), and moyamoya (2%). In the Baltimore-Washington Cooperative Young Stroke Study, ICH was due to AVMs (29%), hematologic causes (23%), vasculopathy (18%), surgical complications (12%), coagulopathy (6%), and indeterminate causes (12%).

Diagnosis

Childhood Arterial Ischemic Stroke

Patients who present with new focal neurologic deficits should undergo an urgent CT scan of the head to rule out acute hemorrhage. Early ischemic stroke may not be seen on head CT and should be confirmed with MRI. In children with moyamoya disease, transcranial Doppler (TCD) may be useful to follow for

stability or progression of vascular disease. (class IIb, level of evidence C). Arteriopathies are a common causes of childhood stroke, so an MRA should be performed as part of the evaluation of a child with a stroke. Cerebral angiography should be considered in cases where the MRA is not informative.

Childhood Cerebral Sinovenous Thrombosis

Presenting symptoms are often diffuse and nonspecific. In series of children with CSVT, the most common presenting symptoms are headache, vomiting, and visual symptoms. Presenting symptoms may overlap with traditional symptoms of idiopathic intracranial hypertension. Other presenting symptoms are lethargy, malaise, irritability, poor appetite, limb weakness, unsteady gait, and seizures.

Common clinical signs on presentation are papilledema, seizure, fever, sixth nerve palsy, and hemiparesis (Fig. 149.3). Other signs include a decreased level of consciousness, visual field defects, cranial nerve palsies, ataxia, speech impairment, and hemisensory loss.

The diagnosis is often delayed. A retrospective chart review of 21 children treated from 1997 to 2005 found that there was a mean of 6 days from onset of symptoms to hospital presentation, and from hospital presentation to diagnosis, there was a mean of 3 days.

There are pathognomonic imaging signs for CSVT. The cord sign is due to dense cortical veins or thrombosed sinuses. The dense-triangle sign due to acutely congealed blood is a very early and transient sign. The delta- or empty-triangle sign is a late finding and is the result of venous flow in the collateral veins in the walls of the sinus compared with absent flow within the sinus.

CT scan is widely available and can be obtained rapidly. At many centers, good quality images can now be obtained with low radiation. In one study, unenhanced CT scan was 73% sensitive for CSVT, and there were no false-positive results. CT venogram increases the sensitivity of the study to detect thrombus in the vein and may be superior to magnetic resonance venogram in visualization of cerebral veins but requires skilled technicians for appropriate timing of the contrast bolus to avoid arterial contamination. It is also affected by poor cardiac output and conditions associated with increased circulation time.

MRI is superior for the evaluation of parenchymal abnormalities. MRI and magnetic resonance venogram do not require contrast, but contrast can be helpful to distinguish between a hypoplastic sinus and thrombosis in the lumen. Flow voids can be mistaken for thrombosis where there is slow cerebral flow.

In children with CSVT, approximately one-quarter have no parenchymal involvement, one-third have ischemic infarcts, and one-third have ICH. Intraventricular and SAHs are seen in less than 10%.

Childhood Intracranial Hemorrhage

Children with nontraumatic brain hemorrhage should undergo a thorough risk factor evaluation. When noninvasive imaging does not demonstrate a nidus, conventional cerebral angiography should be performed. For a patient who presents with symptoms that could be explained by an aneurysm, computed tomography angiography or conventional angiography may be considered even if the patient's MRA fails to show evidence of an aneurysm.

FIGURE 149.3 Cerebral sinovenous thrombosis in a 14-year-old boy with a history of migraine headaches. His headaches markedly worsened over a 3-week period, and he presented to the emergency room with right hand weakness and papilledema. **A:** Sagittal T1 weighted noncontrast magnetic resonance imaging of the brain shows thrombus in the superior sagittal sinus and straight sinus *(arrows)*. **B:** Diffusion-weighted imaging showing diffusion restriction in the left centrum semiovale. His father had a history of deep venous thrombosis, but no clear hypercoagulable state was identified. He was treated with anticoagulation for a year with complete resolution of symptoms.

Management

Childhood Arterial Ischemic Stroke

Acute care after AIS begins with maintenance of normal oxygenation, normothermia, normoglycemia, and control of systemic hypertension. It is reasonable to treat dehydration and anemia. There is no evidence that in children with normal oxygenation, supplemental oxygen provides benefit, and in children without clinical or electrographic seizures, prophylactic administration of antiepileptic medications is not necessary. There is no data confirming the safety and efficacy of hypothermia as an acute treatment for stroke.

Initial therapy in children without SCA should be UFH or LMWH or aspirin (1-5 mg/kg/d) until dissection and embolic causes have been excluded. Once excluded, daily aspirin prophylaxis (1-5 mg/kg/d) for a minimum of 2 years should be continued. In children receiving aspirin who have recurrent AIS or TIAs, consider changing to clopidogrel or an anticoagulant.

Hyperacute stroke therapies include intravenous tissue plasminogen activator (tPA), and endovascular thrombectomy remain controversial in children. The 2015 American Heart Association stroke guidelines support the use of mechanical thrombectomy in select patients younger than 18 years of age up to 6 hours after stroke onset. In 2018, the American Heart Association stroke guidelines extended the window of mechanical thrombectomy in suitable adults up to 24 hours from stroke onset based on the DAWN and DEFUSE-3 trials but did not extend the window in children with stroke. A review of 29 pediatric patients who underwent mechanical thrombectomy with an average age of 10 years showed a significant improvement in National Institutes of Health Stroke Scale scores with no major complications. Despite the lack of evidence, it is not unreasonable to consider mechanical thrombectomy in a child younger than 18 years old up to 24 hours after the stroke onset. Intravenous tPA is an established and effective treatment for adults with stroke if treated within 4.5 hours. A recent consensus statement from the American Heart Association/American Stroke Association recommended consideration of hyperacute therapies such as intravenous tPA and endovascular thrombectomy in children meeting the following criteria: (1) persistent disabling neurologic deficits (pediatric National Institutes of Health Stroke Scale ≥6), (2) radiographically confirmed large-artery occlusion, (3) larger children (due to the size of catheters relative to the size of arteries), (4) treatment decisions made by neurologists with expertise in the treatment of childhood stroke, and (5) interventions by endovascular surgeons also with expertise in the treatment of pediatric stroke.

A child who has suffered a stroke should be enrolled in age-appropriate rehabilitation and therapy program. Cognitive and behavioral performance is especially important in school-aged children. Neuropsychological assessment is useful for planning therapy and educational programs and monitoring cognitive, behavioral, and language deficits after a stroke.

Craniocervical Arterial Dissection

The American Heart Association Stroke Council recommends beginning treatment of an extracranial CCAD with UFH or LMWH and to continue subcutaneous LMWH or bridge to warfarin for 3 to 6 months of treatment. The American College of Chest Physicians recommends anticoagulant therapy for at least 6 weeks, with ongoing treatment dependent on radiologic assessment. One can also consider using an antiplatelet agent instead of LMWH or warfarin. Beyond 6 months, for recurrent symptoms, it is reasonable to continue anticoagulation or an antiplatelet agent. If symptoms have resolved but there is residual abnormality of the dissected artery on imaging, it is also reasonable to continue an antiplatelet agent beyond 6 months. Surgical procedures may be considered for symptoms due to CCAD despite optimal medical therapy. For an intracranial dissection and for SAH resulting from CCAD, anticoagulation is not recommended.

Moyamoya Arteriopathy

With moyamoya disease, surgical revascularization can effectively reduce the risk of stroke. Children with moyamoya should be referred to an appropriate center for consideration of revascularization. There is less literature to recommend one surgical procedure over another, but indirect revascularization may be preferred in younger children whose small-caliber vessels make direct anastomosis difficult, and direct bypass techniques may be preferable in older individuals. Indications for revascularization surgery include progressive ischemic symptoms, evidence of inadequate perfusion, or collateral reserve. After revascularization surgery or in asymptomatic individuals with moyamoya disease, aspirin may be considered. In general, anticoagulants are not recommended with moyamoya disease because of the risk of hemorrhage and the difficulty of maintaining therapeutic levels in children.

Supportive care in children with moyamoya disease includes techniques to reduce anxiety and pain that could lead to hyperventilation-induced vasoconstriction. Preoperative and perioperative hydration is often used with revascularization surgery. Perioperative and intraoperative avoidance of hypotension, hypovolemia, hyperthermia, and hypocarbia may reduce the risk of perioperative stroke.

Cardiogenic Stroke

Treatment for congestive heart failure and congenital heart lesions is recommended and may reduce the likelihood of cardiogenic embolism. This includes resection of an atrial myxoma and does not yet apply to PFOs. It is reasonable to begin anticoagulation following a cardiac embolism in children who are judged to have a high risk for recurrence. UFH or LMWH can be introduced as a bridge to warfarin. LMWH can be continued instead of warfarin, and it is reasonable to continue either LMWH or warfarin for at least 1 year or until the lesion responsible for the risk has been corrected. For a suspected cardiac embolism with an unknown or lower risk of stroke and that is unrelated to a PFO, it is reasonable to treat with aspirin for at least 1 year. It is reasonable to close large atrial septal defects (excludes PFOs) to prevent stroke.

In patients with endocarditis of a prosthetic valve, it may be reasonable to continue long-term anticoagulation. Anticoagulation should not be used for native valve endocarditis, and it is not necessary to remove a cardiac rhabdomyoma in an individual who has been asymptomatic.

Inherited Thrombophilic State

In children with AIS or CSVT, it is reasonable to measure the serum homocysteine level and to introduce therapies such as diet and supplementation of folate, vitamin B_6, or vitamin B_{12} to lower elevated homocysteine values. In an adolescent with AIS or CSVT, it is reasonable to discontinue oral contraceptives.

Other Causes

Children with Fabry disease should receive a-galactosidase replacement therapy.

Childhood Cerebral Sinovenous Thrombosis

Recommendations on anticoagulant use are based on retrospective analysis. While we await a prospective study on anticoagulant use in neonates, a large single-center retrospective analysis of 162 neonates and children from 1992 to 2005 suggests benefit for anticoagulant use even with preexisting hemorrhage. The study was conducted at an institution where a protocol was initiated in 1995 and was practiced. All neonates and children without significant ICH received anticoagulation. If anticoagulation was not started because of significant ICH, a follow-up study was done at 5 to 7 days for clot stability. If the follow-up imaging showed clot propagation, these patients were treated with anticoagulation despite significant ICH. Within 2 weeks of diagnosis, the thrombus propagated in 7% of treated children and 37% of untreated children. Propagation was symptomatic in 60% of children and associated with more severe deficits at discharge. Anticoagulant-related ICH occurred in 5% of treated children and 98% of ICH with anticoagulation occurred in patients with pretreatment ICH. ICH as a complication of anticoagulation was most commonly a subdural hemorrhage and almost all bleeds occurred with additional factors such as supratherapeutic anticoagulation, hypertension, thrombocytopenia, ventriculoperitoneal shunt surgery, and cerebral atrophy.

The acute management of children with CSVT should include hydration, control of clinical and subclinical seizures, and treatment of elevated intracranial pressure. With severe or longstanding increased intracranial pressure, there is a risk for vision loss. Visual fields and visual acuity should be periodically assessed and appropriate measures to control elevated intracranial pressure should be instituted. Monitoring the intracranial pressure may be considered during the acute phase of CSVT.

Bacterial infection and anemia are treatable causes of CSVT, so children with a suspected bacterial infection should receive appropriate antibiotics and a complete blood count should be performed. There may be benefit to diagnostic testing for underlying infections with blood cultures and sinus radiographs. Performing a thorough thrombophilic screen may be beneficial, and its results could affect the risk of rethrombosis and influence therapeutic decisions. In children who have an impaired mental status and are paralyzed or sedated, subclinical seizures are not uncommon. Continuous electroencephalography monitoring may be considered for these patients.

The American Heart Association Stroke Council suggests that it is reasonable to institute either UFH or LMWH whether or not there is secondary hemorrhage, followed by warfarin therapy for 3 to 6 months. Follow-up neuroimaging studies in children with CSVT to confirm vessel recanalization or recurrence of the thrombus may be beneficial. The American College of Chest Physicians recommends initial anticoagulation with UFH or LMWH only in children without significant ICH, followed by LMWH or a vitamin K antagonist for a minimum of 3 months. If after 3 months of therapy, there is incomplete radiologic recanalization of CSVT or ongoing symptoms, anticoagulation should be continued for an additional 3 months. In children with significant hemorrhage, there is a suggestion to repeat the radiologic evaluation at 5 to 7 days and if there is propagation of thrombus, institute anticoagulation.

There are case series describing local cerebral thrombolysis for CSVT. Reported cases suggest that there may be benefit in the hands of experienced interventionalists, but there may also be a considerable risk for hemorrhagic complications. The American Heart Association Stroke Council suggests that in selected children, administration of a thrombolytic agent can be considered. The American College of Chest Physicians suggests thrombolysis, thrombectomy, or surgical decompression only in children with severe CSVT in whom there is no improvement with initial UFH therapy. In children with CSVT and ongoing risk factors for thrombosis, such as nephrotic syndrome, or l-asparaginase therapy, prophylactic anticoagulation is suggested.

Childhood Intracranial Hemorrhage

Children with a severe coagulation factor deficiency should receive appropriate factor replacement therapy, and children with less severe factor deficiency should receive factor replacement after trauma. There is a recommendation to identify and correct, where clinically feasible, congenital vascular anomalies. Recently, a randomized trial of uUnruptured brain arteriovenous malformations in adults found that medical management alone was superior to interventional therapy for patients with unruptured AVMs. This study is changing treatment practice for unruptured AVMs.

The child with an acute brain hemorrhage requires urgent care. Attention should be toward assessment of respiratory effort, control of systemic hypertension, control of clinical and subclinical seizures, and managing increased intracranial pressure. In general, surgical evacuation of a supratentorial intracerebral hematoma is not recommended. Surgery is reasonable in selected patients at risk for cerebral herniation or who have extremely elevated intracranial pressure; however, it is not clear whether this improves the outcome. Acute hydrocephalus with an ICH requires ventricular drainage. If hydrocephalus persists beyond the acute period, shunting may be indicated. Low platelet counts should be corrected, and vitamin K should be administered for vitamin K–dependent coagulation disorders. In the ongoing acute care of patients with SAH, measures to control cerebral vasospasm may be beneficial.

It is reasonable to follow-up asymptomatic individuals who have a condition that predisposes them to intracranial aneurysms with a cranial MRA every 1 to 5 years, depending on the perceived level of risk posed by an underlying condition. Given the possible need for repeated studies over a period of years, computed tomography angiography may be preferable to conventional angiogram for screening individuals at risk for aneurysm.

Outcome

Childhood Arterial Ischemic Stroke

Neurologic Deficits

A child who has suffered a stroke should be enrolled in age-appropriate rehabilitation and therapy program. Cognitive and behavioral performance is especially important in school-aged children. The pediatric stroke outcome measure is based on a detailed age-appropriate, neurologic exam and scored for four domains: sensorimotor deficit, language deficit—production (excludes dysarthria), language deficit—comprehension, and cognitive or behavioral deficit. The weight of language and cognitive and behavioral deficits is considerably greater, and motor deficits are less weighty compared with similar adult stroke

outcome measures. Neuropsychological assessment is useful for planning therapy and educational programs and monitoring cognitive, behavioral, and language deficits after a stroke.

In one single-center series of 90 children followed for a mean of 2 years after an AIS, 49% were either normal or mildly impaired on the pediatric stroke outcome measure.

Recurrence

In northern California, the 5-year cumulative recurrence rate was 19% after childhood AIS. All of the recurrences occurred among children with a vascular abnormality. In a large single-center series, 37% of children had a recurrent AIS or TIA at a median of 267 days (range 1 d to 11.5 y). Of the 84% of patients who had reimaging, 11% had clinically silent recurrent ischemia. Among children with arteriopathy in northern California, the 5-year cumulative recurrence rate was 66%. Factors associated with silent reinfarction and clinical recurrences were moyamoya, low birth weight, genetic thrombophilia, previous TIA, bilateral infarction, preexisting condition, and leukocytosis.

Epilepsy

Poststroke seizures and epilepsy is considerable in children. A number of different studies from different continents show that the frequency of poststroke epilepsy in childhood stroke is between 7% and 29.2%. The rate of poststroke seizure is higher.

Childhood Cerebral Sinovenous Thrombosis

In large-center series, anticoagulation is not associated with increased mortality or severe neurologic outcomes.

Recanalization

At 3 months, more than half of children have recanalization of thrombosed vein. A prothrombotic disorder is associated with no recanalization.

Recurrence

Recurrence occurs in 5% to 17% of children. This may depend on the course of the underlying risk factors and residual patency of the cerebral venous system.

Neurologic Deficits

Poor neurologic outcomes after CSVT include chronic intracranial hypertension, frequent headaches, cognitive difficulties, hemiparesis, reduced visual acuity, isolated sixth nerve palsy, and epilepsy in 5% to 8%. Predictors for good outcome are anticoagulation treatment, older age, no parenchymal abnormality on imaging, and lateral sinus involvement.

In a small cohort of children followed for a mean of 2.1 years after a CSVT, 79% were either normal or mildly impaired. In a larger series of children, outcome was unfavorable in 37%.

Mortality

Mortality is reported between 5% and 12%. In one series of children, most of whom were not treated with anticoagulation, early mortality was 18%.

Childhood Intracranial Hemorrhage

Neurologic Deficits

Disability is more prevalent after childhood ICH than other forms of stroke. In a single-center prospective cohort study at a median follow-up of 3.5 months, 71% of survivors had neurologic deficits, and 55% had clinically significant disability. A prospective cohort from three centers found severe disability in 12%, moderate disability in one-half, and good recovery in only one-third.

Recurrence

In a population-based study from northern California, the 5-year cumulative recurrence rate was 10%. Sixty-four percent of recurrences were within the first 6 months. Children with idiopathic hemorrhage had no recurrences, compared with children with a structural lesion such as a vascular malformation or tumor who had a 5-year cumulative recurrence rate of 13%.

Epilepsy

In one study, at 2 years, epilepsy developed in less than 15%. A risk factor for late seizures and epilepsy was elevated intracranial pressure requiring acute intervention.

Mortality

Childhood ICH confers mortality in approximately 5%.

SICKLE CELL ANEMIA

The process of neurologic injury that confers long-term cognitive and focal impairment in SCA begins in childhood. Neurologic complications of sickle cell disease include cognitive deficit, ischemic and hemorrhagic stroke due to arterial and venous thrombus, sickle cell arteriopathy, and white matter T2 hyperintensity on brain imaging.

Epidemiology

The Cooperative Study of Sickle Cell Disease, the largest series of stroke in SCA, showed that by the age of 20 years, the risk of stroke was 11%, and peak incidence was from 2 to 5 years. There were no gender differences in stroke incidence. In SCA, the annual incidence of stroke is orders of magnitude greater than other childhood stroke. The Baltimore-Washington Cooperative Young Stroke Study found an annual incidence of 285 per 100,000.

Pathobiology

At low oxygen tension, sickle cell hemoglobin polymerizes to form an elongated and rigid sickle shape. This translates to high blood viscosity and the potential for endothelial damage. Sickle cell arteriopathy may be the most important determinant of stroke risk. Over time, arteriopathy tends to progress. Children with a history of stroke were more likely to have progressive vasculopathy than children with abnormal TCDs but no history of stroke. Silent ischemia is twice as common as clinical strokes and confers a high risk for recurrent stroke. Sickle-related arteriopathy more often takes the form of moyamoya arteriopathy with high-grade internal carotid and proximal circle of Willis artery occlusive disease and collateral formation. Older children and adults are at risk for aneurysms, dolichoectasia, and SAH.

The combination of risk factors that result in vascular disease and stroke are still not fully understood. Risk factors such as infection, elevated leukocyte count, acute chest syndrome, inflammation, low hemoglobin concentration, and nocturnal desaturations may all contribute to the risk for stroke in SCA.

Single-nucleotide polymorphisms in genes for a tumor necrosis factor promoter, interleukin-4 receptor, β_2-adrenoceptor, leukotriene C4 synthase, vascular cell adhesion molecule 1, and low-density lipoprotein receptor are all reported in association with stroke in children with SCA. These genes are involved in inflammatory pathways.

Diagnosis

The American Heart Association/American Stroke Association guidelines (2011) recommend TCD for selection of children for primary stroke prevention LEVEL 1.[1] MRI and MRA are not similarly established.

Management

The only class I recommendations for primary pediatric stroke prevention is in SCA. The recommendations largely derive from the STOP I and II randomized controlled trials. The STOP I trial enrolled children with SCA, mean TCD velocity in the ICA or MCA of 200 cm/s or greater, and no history of stroke. Patients were randomized to periodic blood transfusions versus standard of care. The study was terminated prior to completion because the results were highly significant. In the standard of care arm, there were 10 ischemic and 1 hemorrhagic strokes, compared with the transfusion arm where there was 1 ischemic stroke. Periodic transfusions reduced the risk of stroke by 92%. There is a recommendation to begin TCD screening at 2 years LEVEL 1.[1] TCD should be performed annually, and abnormal studies should be repeated in 1 month. Borderline and mildly abnormal TCD studies may be repeated in 3 to 6 months. For TCD velocity greater than 200 cm/s, even in children without a clinical stroke, regular transfusions are recommended to reduce the risk of stroke in children 2 to 16 years of age LEVEL 2.[1] Children with a confirmed infarction should also receive regular red cell transfusion in conjunction with measures to prevent iron overload. Prior to undergoing a cerebral angiogram, all children with SCA should be treated with a red blood cell transfusion to reduce red blood cell sickling precipitated by the procedure.

When routine transfusions became accepted clinical practice for abnormal TCDs or history of a stroke, the question of when one could safely stop transfusions became widely relevant. Seven years after STOP I, STOP II published its findings. Patients with greater than 30 months on transfusion therapy, no history of a clinical stroke, and reversion to a low-risk TCD (<170 cm/s) were randomly assigned to continuation or discontinuation of transfusions. Again, the trial was stopped early. Of 41 patients in the discontinuation group, 14 developed a high-risk TCD over a mean of 4.5 months, and 2 had a stroke. Neither outcome occurred in the continuation group. A long-term transfusion program is currently recommended LEVEL 3.[2]

There is ongoing research on hydroxyurea as an alternative to routine transfusions. Hydroxyurea increases fetal hemoglobin and mean corpuscular volume, and it decreases reticulocytes, white blood cells, and platelets. In the TCDs with transfusions changing to hydroxyurea trial, hydroxyurea was found to be noninferior compared to the transfusion protocol.

Myeloablative stem cell transplantation if successful could reverse high TCD velocities and almost eliminate the risk of stroke in children. Transplantation requires a matched donor, and even if one is identified, rejection and morbidity are considerable. In children at high risk for stroke, particularly those who are not candidates for transfusion, it might be reasonable to consider bone marrow transplantation, but this should be done in a clinical trial setting.

In children without SCA and moyamoya arteriopathy, revascularization is an effective treatment for prevention of recurrent stroke. The data in children with SCA and moyamoya arteriopathy is more limited but suggests benefit. The American Heart Association/American Stroke Association recommendation is to consider surgical revascularization as a last resort in cases where there is cerebrovascular dysfunction despite optimal medical management.

Acute management of ischemic stroke should include hydration, correction of hypoxemia, and correction of systemic hypotension. An exchange transfusion to reduce sickle hemoglobin to less than 30% of the total hemoglobin is reasonable. A vascular lesion should be considered when there is an ICH. There are no data to indicate that periodic transfusions reduce the risk of ICH caused by sickle cell disease.

Outcome

Neurologic Deficits

Compared with healthy children, children with SCA have deficits in working memory and processing speed on neurocognitive testing.

Recurrence

Untreated, the risk of recurrent stroke may be 50%.

Mortality

Overall stroke-related mortality is approximately 10%, and in the 2 weeks after a hemorrhagic stroke, mortality is as high as one-quarter.

GENETICS OF STROKE IN CHILDREN

Stroke genetics is a rapidly expanding field because several genetic pathways have been identified in the last decade that provide insight into angiogenesis and blood vessel function. These disorders can be categorized as follows:

Disorders with Abnormal Angiogenesis

Mutations in these genes leading to AVMs, aneurysms, and cerebral cavernous malformations (CCMs). RASA1 mutation can cause cerebral AVMs. Hereditary hemorrhagic telangiectasias, particularly the ENG and ACVRL1 mutations, can also lead to brain AVMs. Several disorders cause CCM1, CCM2, and CCM3. Rupture of CCMs can lead to spontaneous ICHs and stroke.

Disorders of Vessel Wall Stenosis

These disorders typically lead to moyamoya arteriopathy. In these cases, there is proliferation of components of the blood vessel wall, causing gradual stenosis of the vessel, ischemia in the region of the brain supplied by the blood vessel, and formation of moyamoya collaterals. These disorders are described above in the section on moyamoya syndrome (see Table 149.2).

Connective Tissue Disorders

In these disorders, the blood vessels form appropriately but the connective tissue supporting the vessel is unusually weak and prone to dissection. Ehlers-Danlos type IV and osteogenesis imperfecta type I are the best-known examples, but there are several similar connective tissue disorders that can present with spontaneous cerebral arterial dissection. COL4A1 mutation, which affects type IV collagen, falls into this category and can present in neonates with intrauterine stroke and porencephaly.

Thrombophilic Disorders

These hematologic conditions disrupt the normal balance between clot formation and clot breakdown and predispose children to AIS, CSVT, and ICH. Examples include PTG20210, factor V Leiden, MTHR, and protein C deficiency.

Genetic or Metabolic Stroke or Stroke-like Episodes

Some examples include PHACE syndrome, Fabry disease, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes, and POLG1 gene mutations. Stroke has also been described in organic acidurias (methylmalonic, propionic, isovaleric, and glutaric aciduria type II) and congenital disorder of glycosylation type Ia. It sometimes can be unclear in these disorders whether the stroke is due to the metabolic condition affecting the brain vasculature directly, the brain parenchyma directly, or both.

Family members with clotting disorders or strokes at a young age may clue the clinician into considering one of these genetic disorders. On physical examination, skin telangiectasias or hyperextensible joints are also highly suggestive of a genetic condition leading to stroke. If any of these factors are present, the clinician should pursue a genetic evaluation.

Brain Tumors in Children 150

James H. Garvin, Jr

KEY POINTS

1. Primary brain tumors are the second commonest childhood cancer (after leukemia) and the leading cause of cancer-related death.
2. Low-grade astrocytomas are the largest group of primary brain tumors in children, followed by medulloblastoma, high-grade astrocytoma, and ependymoma. The risk is increased in syndromes such as neurofibromatosis.
3. The diagnostic classification of childhood brain tumors was revised substantially in 2016 to integrate emerging molecular findings.
4. Survival of children with brain tumors is approximately 70% overall and has improved substantially for medulloblastoma but remains poor for high-grade astrocytoma and especially diffuse intrinsic pontine glioma.
5. Current research focuses on identification of molecular targets for novel therapies, improved drug delivery, radiation-sparing treatment strategies, and quality of survival.

INTRODUCTION

Childhood brain tumors range from benign congenital lesions to aggressive, infiltrative cancers. Malignant brain tumors are the most common solid tumor cancers of childhood, the second most common cancer overall (after leukemia), and the leading cause of death. Limitations to cure include tumor resectability, brain tolerance of radiation therapy, and limited chemotherapy penetration of the blood-brain barrier. Treatment sequelae may seriously compromise quality of survival. Nonetheless, research advances and refinement of treatment techniques continue to give a sense of cautious optimism. Current research focuses on radiation-sparing treatment strategies, improved drug delivery, and identification of molecular targets for novel therapies. A prevailing concept is that malignant brain tumors are propagated from stemlike progenitor cells, with transcriptional programs mirroring those of normal neuronal and other lineages but stalled in development. These tumor progenitor cells may be intrinsically resistant to standard radiation and chemotherapy but could be eliminated by targeted therapy with agents, which disrupt critical signaling pathways or induce differentiation.

EPIDEMIOLOGY

Incidence

Malignant and nonmalignant central nervous system (CNS) tumors may arise at any time in infancy and childhood. Most pediatric brain tumors occur in the first decade of life. Location is predominantly cerebral/ventricular in infants, cerebellar/brainstem in young children, and midbrain/cerebral in older children and adolescents (**Fig. 150.1A,B**). Incidence rates are tracked by the Central Brain Tumor Registry of the United States. The incidence rate of primary malignant and nonmalignant CNS tumors in the United States in children ages 0 to 14 years is 5.65 cases per 100,000 (approximately 3,500 per year). For adolescents and young adults ages 15 to 39 years, the corresponding incidence rate is 11.2 cases per 100,000 (approximately 12,000 per year). Malignant CNS tumors account for about 25% of all cancer diagnoses in children ages 0 to 14 years, and 17% of cancer cases in adolescents ages 15 to 19 years (about 20% of childhood cancer overall).

The incidence of childhood brain tumors worldwide is highest in the United States. Here, the incidence is higher in non-Hispanic whites and Asian-Pacific islanders than blacks, Hispanics, and American Indian/Alaskan natives. The annual incidence of childhood brain tumors in the United States increased by 35% between 1973 and 1994, led mainly by supratentorial low-grade astrocytomas and brainstem tumors diagnosable by magnetic resonance imaging (MRI), which became widely available in the mid-1980s, displacing computed tomography (CT). Data for 1998-2013 show stable incidence rates for children ages 0 to 19 years, with modest trends toward increased pilocytic astrocytomas and decreased CNS embryonal tumors. A separate analysis showed increased incidence of malignant CNS tumors in children from 2000 to 2010 and in adolescents from 2000 to 2008. However, these findings may be attributable to changes in identification, reporting, and classification, rather than true changes in incidence.

Childhood brain tumor survival rates vary widely, from highly curable cerebellar pilocytic astrocytomas to lethal diffuse intrinsic pontine gliomas (DIPGs). (Note that *glioma* is an umbrella term used to describe the different types of tumors arising from the glial or supporting tissue of the brain, including astrocytoma, oligodendroglioma, and glioblastoma.) Brain tumors vary in their clinical aggressiveness. Some are slow-growing and are likely to be curable. Others are rapidly growing, invasive, difficult to treat, and likely to recur. Categorization of primary brain tumors as malignant or benign does not always reflect clinical behavior. Certain histologically benign lesions such as craniopharyngioma may cause extensive brain damage and endocrine dysfunction, whereas low-grade astrocytomas are rarely life-threatening but can progress to high-grade gliomas, at least in adults. Moreover, tumorigenesis of high-grade astrocytomas in children differs from adult glioblastoma, as deduced from comparative genomic hybridization studies.

Histologies

Astrocytomas are the largest group of primary CNS tumors in children age 0 to 14 years, mostly of low-grade histology (World Health Organization [WHO] grades I and II) (**Fig. 150.2A**). Next in frequency are medulloblastomas, the most common

FIGURE 150.2 A: Distribution in children (age 0-14 y) of primary brain and central nervous system tumors by Central Brain Tumor Registry of the United States (CBTRUS) histology groupings and histology (N = 16,366), CBTRUS Statistical Report: NPCR and SEER, 2008-2012. B: Distribution in adolescents (age 15-19 y) of primary brain and central nervous system tumors by histology (N = 6,747), CBTRUS Statistical Report: NPCR and SEER, 2008-2012. Abbreviations: ATRT, atypical teratoid/rhabdoid tumor; NOS, not otherwise specified; PNET, primitive neuroectodermal tumor. [a]Percentages may not add up to 100 due to rounding. [b]Includes oligodendrogliomas and anaplastic oligodendrogliomas. [c]Includes diffuse astrocytoma, anaplastic astrocytoma, and unique astrocytoma variants. [d]Includes choroid plexus tumors, other neuroepithelial tumors, tumors of the pineal region, other tumors of cranial and spinal nerves, mesenchymal tumors, primary melanocytic lesions, other neoplasms related to the meninges, other hematopoietic neoplasms, hemangioma, neoplasm unspecified, and all other. [e]ICD-O-3 histology codes 9380-9384, 9391-9460, and 9480.

high-grade malignant tumor (reported as an embryonal tumor in Central Brain Tumor Registry of the United States), with atypical teratoid/rhabdoid tumors (AT/RTs) and other embryonal tumors previously termed *primitive neuroectodermal tumors* (PNETs). After these are a diverse group of congenital and acquired lesions, including high-grade astrocytomas, ependymomas, craniopharyngiomas, germ cell tumors, and choroid plexus tumors. Neuronal tumors (gangliocytoma) and mixed glioneuronal tumors (ganglioglioma, dysembryoplastic neuroepithelial tumor [DNT]) are relatively uncommon.

The distribution of histologies changes somewhat in older adolescents (age 15-19 y) (**Fig. 150.2B**). The principal primary brain tumors of adults (glioblastoma multiforme, meningioma, oligodendroglioma, pituitary adenoma) are uncommon in young children but begin to emerge in later adolescence.

CNS metastases from solid tumors are also uncommon in children, unlike in adults. Cerebral metastases may occur as late events in pediatric germ cell tumors (13.5% incidence), osteosarcoma (6.5%), neuroblastoma (4.4%), melanoma (3.6%), Ewing sarcoma (3.3%), rhabdomyosarcoma (1.9%), and Wilms tumor (1.3%). CNS involvement by acute leukemia or non–Hodgkin lymphoma can be present at diagnosis and/or relapse, and treatment protocols incorporate prophylactic intrathecal chemotherapy. Primary spinal cord tumors are uncommon in children; the predominant histologies (age 0-19 y) are astrocytomas, ependymal tumors, and neuroepithelial tumors.

Risk Factors

The causes of congenital and childhood CNS tumors remain unknown. ("Congenital" refers to lesions detected prenatally or within the first 60 d of life.) A meta-analysis from 16 international surveys revealed a male-to-female ratio of 1.29. Increased head circumference at birth is positively associated with brain cancer in childhood, with a relative risk of 1.27 per 1-cm increase after adjustment for birth weight, gestational age, and gender, suggesting brain pathology may originate in fetal development. The most common CNS tumors diagnosed in the first year of life are low-grade astrocytoma, medulloblastoma, ependymoma, and choroid plexus tumors.

Most CNS tumors are sporadic, but CNS tumors occur with increased frequency in certain inherited disorders, and other risk-modifying factors have been identified or proposed in nonsyndromic children (**Fig. 150. 3**). Individuals with *neurofibromatosis type 1 (NF-1)* have a 10% chance of developing an intracranial tumor, including optic pathway gliomas and astrocytomas elsewhere in the brain and spinal cord. The incidence of NF-1 is approximately 1 in 3,000 individuals; half of cases are inherited, and the remainder are sporadic. The *NF-1 gene* maps to chromosome 17q11.2, and loss of one NF-1 allele is evident in nearly all NF-1–associated pilocytic astrocytomas but only rarely in sporadic pilocytic astrocytomas, suggesting different mechanisms of tumor formation. In the less common neurofibromatosis type 2 (NF-2) (incidence approximately 1 in 37,000), there is a predisposition to bilateral vestibular schwannomas (acoustic neuromas), with chromosome 22q deletions and *NF-2 gene* mutations in at least half of cases. NF-2 also predisposes to ependymomas, which commonly show a chromosome 22q deletion, but analysis of the *NF-2 gene* in ependymomas has revealed only a single mutation in a tumor that had lost the remaining wild-type allele.

Children with tuberous sclerosis complex (incidence 1 in 5,000-10,000) have benign hamartomas of the brain and are at

FIGURE 150.3 Summary of established and suspected risk factors related to childhood brain tumors. More established risk factors are listed in bold type. Suggested risk factors that are high priority for validation are listed in nonbold type. Abbreviation: SNPs, single nucleotide polymorphisms). (Source: Johnson KJ, Cullen J, Barnholtz-Sloan JS, et al. Childhood brain tumor epidemiology: a brain tumor epidemiology consortium review. *Cancer Epidemiol Biomarkers Prev.* 2014;23[12]:2715-2736.)

risk during childhood for subependymal giant cell astrocytoma (SEGA) or ependymoma. The tuberous sclerosis genes map to chromosomes 9q and 16p, and allelic loss at these loci has been found in some SEGAs, suggesting a tumor suppressor function.

Sturge-Weber syndrome is the third most common neurocutaneous disclusively sporadically due to an activating mutation in GNAQ. Neurologic abnormalities include leptomeningeal angiomas, with case reports of angiomatous meningioma and hypothalamic low-grade astrocytoma.

Hemangioblastomas of the cerebellum, medulla, and spinal cord are associated with von Hippel-Lindau disease, and choroid plexus tumors have occasionally been reported. Loss of chromosome 3p sequences has been described in one choroid plexus tumor, suggesting involvement of the *VHL gene*.

There is an increased risk of brain tumors in the Li-Fraumeni syndrome, particularly choroid plexus carcinoma (CPC) but also astrocytoma. Li-Fraumeni syndrome involves germ line mutations in the p53 tumor suppressor gene on chromosome 17 and predisposes to many other cancers.

Gorlin syndrome (nevoid basal cell carcinoma syndrome), resulting from *PTCH1 gene* mutation, predisposes to medulloblastoma, specifically Sonic Hedgehog (SHH) subtype (see the following discussion). Turcot syndrome describes the association of primary CNS tumors with colorectal polyps, either familial adenomatous polyposis or hereditary nonpolyposis colorectal cancer, due to mutations in the adenomatous polyposis coli (APC) and DNA mismatch repair genes. Familial adenomatous polyposis is associated with medulloblastoma (Turcot syndrome type 2) in childhood, whereas hereditary nonpolyposis colorectal cancer is associated with glioblastoma in young adults (Turcot syndrome type 1).

Cowden syndrome (multiple hamartoma syndrome with germ line phosphatase and tensin homolog [PTEN] tumor suppressor mutation) is associated with dysplastic gangliocytoma of the cerebellum (Lhermitte-Duclos disease), whereas Rubinstein-Taybi syndrome (germ line mutation in CREBBP involved in sonic hedgehog regulation) is associated with meningioma, medulloblastoma, and oligodendroglioma. Ataxia telangiectasia features progressive cerebellar atrophy and has been associated with meningioma in addition to lymphoma and leukemia.

There is a predisposition to pineoblastoma in hereditary retinoblastoma (Rb) ("trilateral retinoblastoma") and also in DICER1 syndrome, which involves mutation in an endoribonuclease responsible for the production of mature microRNAs, small single-stranded RNA molecules that target messenger RNAs (mRNAs) and repress protein synthesis. DICER syndrome also predisposes to pleuropulmonary blastoma and multiple adult-onset cancers. Pituitary adenomas are seen in multiple endocrine neoplasia type 1.

Common genetic variation may also influence tumor susceptibility. Studies investigating birth order, birth weight, presence of congenital anomalies, advanced parental age, maternal diet and prenatal vitamin consumption, familial allergic conditions, and childhood infectious exposures have yielded mixed results or borderline evidence for a positive association, but brain tumor risk is increased in the presence of congenital anomalies of the CNS.

Combined cytogenetic and molecular studies of the common sporadic childhood brain tumors have revealed nonsyndromic genomic alterations potentially contributing to tumorigenesis. Isochromosome 17q is found in half of all medulloblastomas, implicating a tumor suppressor gene. Clinical outcome is now predictable by gene expression profiles. Somatic TP53 mutation in medulloblastoma and overexpression of p53 in high-grade astrocytoma of childhood are associated with adverse outcome. In medulloblastoma, low MYC oncogene mRNA expression and high Trk C neurotrophin-3 receptor mRNA expression identify better prognosis.

The desmoplastic subtype of medulloblastoma is specifically associated with the nevoid basal cell carcinoma syndrome, caused by mutations in the *PTCH1 gene*, a tumor suppressor gene normally encoding patched-1, which blocks cell proliferation unless missing or bound by the Sonic Hedgehog protein, the ligand for the patched-1 receptor. Desmoplastic medulloblastoma in infants from affected families is reported to have a good prognosis. Conversely, the large cell, anaplastic variant of medulloblastoma, and the AT/RT have an unfavorable prognosis. Diagnosis of these variants is based on light microscopic and immunohistochemical findings, and AT/RT is further distinguished by chromosome 22q11 deletion with inactivation of the hSNF5/INI1 gene.

Environmental risk factors for CNS tumors include ionizing radiation, which in the distant past was given even for benign conditions such as tinea capitis. In children treated for acute lymphoblastic leukemia, there is a 1.39% cumulative incidence of secondary brain tumors (gliomas and meningiomas) at 20 years, and cranial irradiation is a dose-dependent predisposing factor, with a latency of 7 to 9 years. Another study with 30-year follow-up found a 3.0% cumulative incidence of brain tumors (excluding meningioma) following acute lymphoblastic leukemia treatment. Radiation therapy in medulloblastoma is also associated with an increased incidence of secondary malignant brain tumors, as high as 4%. Regarding radiation exposure from diagnostic procedures, a retrospective cohort study concluded that although the absolute risk is small, use of CT scans in children with doses of about 60 mGy could triple the risk of brain cancer (estimated 1 excess case per 10,000 head CT scans). There is no conclusive evidence of risk from exposure to electromagnetic fields (from electric blankets, microwave ovens, or cell phones).

Studies have shown an association between farm and animal exposures and childhood brain tumors and a weak association with toxic exposures occurring in the household. Although not implicated in retrospective studies, maternal smoking during pregnancy was associated with slightly increased risk of brain tumors in offspring in a prospective study linking birth and cancer registries. The incidence of medulloblastoma in England declined after 1984 when multivitamin supplementation in pregnancy became widespread following reports that folate reduced the risk of neural tube defects. Maternal intake of folic acid in pregnancy was reported to be protective against medulloblastoma, but this association could not be confirmed in a subsequent study. A seasonal variation in medulloblastoma (but not other brain tumors) was noted in the United States between 1995 and 2001, peaking in October, and a separate study found increased risk of medulloblastoma associated with paternal exposure to any heat source in the 3 months prior to the index pregnancy, redirecting attention to electric blankets. Established and suspected risk factors for childhood brain tumors are summarized in **Figure 150.3**.

Survival

Survival of children with brain tumors is approximately 70% overall and substantially higher for nonmalignant lesions and low-grade tumors but distinctly worse for high grade glioma and especially DIPG (**Table 150.1**).

TABLE 150.1 One-, Two-, Five-, and Ten-Year Relative Survival Rates for Selected Malignant Brain and Central Nervous System Tumors by Age Groups[a]

Diagnosis	Age Group	1 y	2 y	5 y	10 y
Pilocytic astrocytoma	0-14 y	98.7%	98.5%	97.2%	94.9%
	0-19 y	98.5%	98.3%	96.8%	96.2%
Diffuse astrocytoma	0-14 y	91.2%	87.0%	82.7%	80.7%
	0-19 y	92.4%	87.3%	82.7%	80.4%
Anaplastic astrocytoma	0-14 y	58.7%	39.7%	30.4%	25.9%
	0-19 y	62.9%	41.9%	31.0%	26.5%
Glioblastoma multiforme	0-14 y	50.9%	29.1%	22.2	15.2%
	0-19 y	57.2%	32.5%	19.2%	12.6%
Oligodendroglioma	0-14 y	95.8%	95.1%	92.7%	90.1%
	0-19 y	96.8%	94.6%	92.2%	90.1%
Anaplastic oligodendroglioma	0-19 y	84.5%	62.3%	31.0%	26.5%
Ependymoma	0-14 y	93.6%	86.0%	72.2%	62.8%
	0-19 y	94.0%	86.9%	74.7%	64.9%
Oligoastrocytoma	0-14 y	94.6%	86.5%	78.7%	72.5%
	0-19 y	93.4%	86.8%	81.2%	76.1%
Neuronal/neuronal-glial	0-14 y	97.1%	90.6%	87.2%	87.2%
	0-19 y	96.3%	86.3%	84.1%	72.4%
Embryonal	0-14 y	79.9%	70.3%	62.1%	55.5%
	0-19 y	80.9%	71.0%	61.9%	55.8%
All CNS	0-14 y	85.2%	78.0%	72.3%	68.2%
	0-19 y	86.4%	79.1%	73.0%	69.0%

Abbreviation: CNS, central nervous system.
[a]Source: Ostrom QT, Gittleman H, Farah P, et al. CBRTUS statistical report: primary brain and central nervous system tumors diagnosed in the United States in 2006-2010. *Neuro Oncol.* 2013;15(suppl 2):ii1-ii56.

Survival for certain tumors has improved substantially. The best example is medulloblastoma, where survival improved from essentially zero percent to over 50% with the introduction of postoperative craniospinal irradiation in the 1950s, and further improvement has been achieved with the introduction of adjuvant chemotherapy. Postoperative irradiation affords improved survival in ependymoma, and there may be a benefit of neoadjuvant or maintenance chemotherapy (ie, before or after radiation therapy). Combined modality therapy incorporating radiotherapy and high-dose chemotherapy with autologous peripheral blood stem cell rescue has led to improved survival in AT/RT, and intensive chemotherapy with peripheral blood stem cell rescue allows deferral or avoidance of craniospinal irradiation in responding infants with medulloblastoma.

PATHOBIOLOGY

Current research on CNS tumorigenesis is based on the molecular genetics of tumor-associated syndromes, rodent models of pediatric brain tumors, and technologic advances in efforts to identify genes that regulate normal and neoplastic cells in the developing CNS. Although the names of individual brain tumors imply that they originate from normal brain cells (eg, astrocytoma from astrocytes), the primitive embryonal tumors of childhood that arise during brain development more likely result from aberrant regulation of neurodevelopment genes. Recently, it has been postulated that brain tumors, like hematologic malignancies, contain small numbers of stem cells (identified as $CD133^+$), which have marked capacity for proliferation and self-renewal. These stem cells can not only differentiate to phenotypically recognizable brain tumor cells but also maintain clonal proliferation and may be highly resistant to conventional anticancer treatment such as radiation and cytotoxic chemotherapy. Candidate stem cells have been proposed for medulloblastoma, ependymoma, and malignant astrocytomas. Further characterization of brain tumor stem cells may offer new insights into mechanisms of tumorigenesis and lead to novel treatment strategies based on preferential targeting of tumor stem cells.

Sonic Hedgehog, Wnt Signaling, Cerebellar Development, and Medulloblastoma

In the 19th century, Obersteiner described the cells of the external granular layer in the developing cerebellum. Based on morphologic similarity, granule cell precursors (GCPs) were considered the cells of origin in medulloblastoma. Now, gene chip analysis and mouse models have linked medulloblastoma to molecular markers of GCPs. The cerebellum matures through a complex interplay of genes of general CNS development and specifically cerebellar genes. For instance, SHH is a glycoprotein involved in the development of the CNS. In cerebellar development, Purkinje cells secrete SHH to activate genes in GCPs and stimulate proliferation of these cells. Activating mutations of the SHH pathway account for desmoplastic medulloblastoma in the nevoid basal cell carcinoma syndrome (Gorlin syndrome), 10% to 20% of sporadic medulloblastomas, and histologically similar tumors in mice that are heterozygous for the equivalent genes. Genome sequencing of SHH-driven medulloblastomas reveals pathway mutations involving PTCH1 (across all age groups), SUFU (infants, including cases of germ line mutation), and SMO

(in adults). Functional assays in different SHH-driven medulloblastoma xenografts demonstrated that tumors harboring PTCH mutation were responsive to SMO inhibition, whereas tumors with SUFU mutation or MYCN amplification were resistant.

Wnt proteins also play a role in CNS development and have been linked to medulloblastoma. Patients with Turcot syndrome, which involves defects in the APC gene, are susceptible to colorectal and brain tumors, notably medulloblastoma. APC is an element of the Wnt signaling pathway, and up to 30% of spontaneous medulloblastomas show mutations in APC and other components of this neurodevelopmental signaling cascade. Cell nuclear accumulation of β-catenin protein is also associated with activation of Wnt/Wg signaling, and positive immunostain for β-catenin in medulloblastoma has been associated with favorable treatment outcome even with metastatic disease at presentation.

Wnt proteins bind to receptors and modulate C-myc, a transcription factor that promotes cell cycle progression. Activation of C-myc and N-myc leads to proliferation, cell growth, and maintenance of an undifferentiated cellular phenotype; these genes are amplified in some medulloblastomas and are associated with a poor clinical outcome. The same genes are amplified by the SHH pathway. Wnt1 is required for mesencephalon/metencephalon patterning early in development. Cerebellar primordia fail to develop in mice lacking Wnt1, and mutations in other Wnt pathway components have been implicated not only in medulloblastoma but also in colon cancer, hepatocellular carcinoma, and prostate and ovarian cancers.

Deletion of chromosome 17p, the most frequently detected genetic lesion in medulloblastoma, has been identified as a cause of unrestrained hedgehog signaling. This deletion results in loss of REN(KCTD11), a suppressor of hedgehog signaling, thus removing a checkpoint of hedgehog-dependent events during cerebellar development and tumorigenesis. Inactivation of the tumor suppressor p53, also a resident of chromosome 17, may contribute to the growth of tumors resembling medulloblastoma in mice, but there is neither an increased incidence of medulloblastoma in humans lacking p53 nor a change in p53 within the medulloblastoma cells, although somatic p53 mutation confers poor prognosis clinically.

The gene *Bmi1*, which induces leukemia through repression of tumor suppressors, is overexpressed in many medulloblastomas and promotes cerebellar GCP proliferation. Linked overexpression of *Bmi1* and patched (*PTCH*) in primary human medulloblastomas, together with rapid induction of BIM expression on addition of SHH or overexpression of the SHH target Gli1 in cerebellar granule cell culture, implicates Bmi1 overexpression as an alternative or additive mechanism in medulloblastoma pathogenesis.

CD133 identifies medulloblastoma stem cells, and in a mouse model enrichment of CD133 in group 3 medulloblastoma is associated with increased metastasis and poor outcome. The signal transducers and activators of transcription-3 pathway are selectively activated in $CD133^+$ medulloblastoma stem cells and promote tumorigenesis through regulation of c-MYC. Treatment with signal transducers and activators of transcription-3 inhibitors resulted in tumor regression and could represent a potential therapeutic strategy for recurrent group 3 medulloblastoma.

"Classic" medulloblastoma has the histologic appearance of a small, round, blue cell tumor with a diffuse pattern of poorly differentiated cells. Neuroblastic ("Homer-Wright") rosettes may be present, and immunohistochemical staining is usually positive for synaptophysin and occasionally for neurofilament protein or glial fibrillary acidic protein (GFAP), although the latter usually represents reactive intratumoral astrocytes. Desmoplastic/nodular medulloblastoma typically arises in cerebellar hemispheres and is characterized by nodular islands of differentiating neuroblasts; an "extensively nodular" variant is recognized in infants. Large cell/anaplastic medulloblastoma comprises large neoplastic cells with vesicular nuclei and prominent nucleoli. About one-quarter exhibit at least moderate anaplasia and show aggressive clinical behavior.

A specific chromosome abnormality, isochromosome 17q (ie, duplication of the long arm or deletion of the short arm of chromosome 17), is seen in half of cases of medulloblastoma. This could result in inactivation of a tumor suppressor gene located on chromosome 17 but is distinct from p53. It is unclear whether chromosome 17p deletions impart poor prognosis, but diploid tumors have worse outcome than aneuploid or hyperdiploid tumors.

The 2016 revision of the WHO classification of CNS tumors now incorporates the molecular subgroups of medulloblastoma as distinct entities (**Fig. 150.4**): (1) Wnt tumors (named for drosophila wingless) with classic histology and very good prognosis; (2) SHH tumors (named for Sonic Hedgehog), relatively more common in infants and adults, with desmoplastic/nodular histology and intermediate prognosis (good in infants); (3) "group 3" tumors with overrepresentation of large cell/anaplastic (LC/A) histology, MYC amplification, very frequent metastasis, and poor prognosis; and (4) "group 4" tumors with classic histology but tendency for metastasis, occasional MYCN amplification, and intermediate prognosis.

Immunohistochemical correlations are nuclear positivity for β-catenin in Wnt tumors, GAB1 positivity in SHH tumors, and filamin A and YAP1 positivity in both. Correlation with cytogenetic findings shows isochromosome 17q to be typical of group 3 and 4 tumors, monosomy 6 associated with Wnt tumors, and 9q and 10q deletion in SHH tumors. Profiling six fluorescent in situ hybridization biomarkers (GLI2; MYC; and chromosomes 11, 14, 17p, and 17q) reliably identifies very low-risk and very high-risk patients within SHH, group 3, and group 4 medulloblastomas. Exam sequencing has revealed subtype-specific somatic mutations in known medulloblastoma-related genes (CTNNB1, PTCH1, MLL2, SMARCA4) and genes not previously considered medulloblastoma-related (DDX3X, CTDNEP1, KDM6A, TBR1).

Wnt-activated medulloblastomas occur mainly in older children, represent 10% of all medulloblastomas, and have the best prognosis. Expected findings are β-catenin nuclear staining, 6q loss, and/or CTNNB1 mutation. APC mutation should prompt germ line testing for Turcot syndrome.

SHH-activated medulloblastomas have bimodal age distribution (younger than age 3 y and adolescent), represent 30% of medulloblastomas, and have good prognosis in infants but intermediate in adolescents. Expected findings are desmoplastic/nodular histology, 9q deletions, and mutations in SHH pathway genes (PTCH1, PTCH2, SMO, SUFU, and GLI2). Infant SHH includes two subtypes, one with focal amplifications and frequently metastasizing and a second with distinctive histology (medulloblastoma with extensive nodularity) and good prognosis. SHH-activated tumors in children age 3 to 16 years are enriched for MYCN and GLI2 amplification and TP53 mutation and have worse prognosis (<50% survival).

Non-Wnt/non-SHH medulloblastoma includes two subgroups. Group 3 medulloblastoma (20% of all cases) shows male preponderance, infant and childhood age, frequent metastatic presentation, large cell/anaplastic histology, isochromosome 17, MYC amplification, and poor prognosis (<50% survival).

FIGURE 150.4 Molecular subgroups of medulloblastoma. (Source: Kool M, Korshunov A, Remke M, et al. Molecular subgroups of medulloblastoma: an international meta-analysis of transcriptome, genetic aberrations, and clinical data of WNT, SHH, group 3, and group 4 medulloblastomas. *Acta Neuropathol.* 2012;123:473-484.)

Patients whose tumors show large cell/anaplastic histology without MYC amplification have better prognosis (70% survival). Group 4 medulloblastoma (40% of cases) shows male preponderance, infant to adolescent age, metastatic presentation, classic or large cell/anaplastic histology, MYCN or CDK6 amplification, and intermediate prognosis.

The term *supratentorial primitive neuroectodermal tumor* (sPNET), implying a histologic counterpart of medulloblastoma occurring outside the posterior fossa and tending to disseminate via cerebrospinal fluid (CSF) pathways, was eliminated in the 2016 WHO Classification of CNS tumors, which emphasizes integrated phenotypic and genotypic diagnosis. Fully 31% of PNETs were reclassified as high-grade gliomas, based on shared genetic and epigenetic mutations or copy number alterations. Meanwhile, a molecularly distinct group was created: embryonal tumor with multilayered rosettes (ETMR), chr19q13.41 microRNA cluster (C19MC)-altered, and histologically similar tumors without C19MC alteration. This group of aggressive lesions arising mainly in toddlers includes embryonal tumor with abundant neuropil and true rosettes, ependymoblastoma, and medulloepithelioma (collectively 11% of the total). Pineoblastoma is now categorized as a pineal parenchymal tumor, which can be associated with germ line mutations in RB1 ("trilateral retinoblastoma") or DICER1.

Four new distinct entities were introduced in WHO 2016, accounting for 24% of the total: CNS neuroblastoma with FOXR2 activation, CNS Ewing sarcoma family tumor with CIC alteration, CNS high-grade neuroepithelial tumor with MN1 alteration, and CNS high-grade neuroepithelial tumor with BCOR alteration (**Fig. 150.5**).

Three molecular subgroups were proposed based on differential expression of cell lineage markers LIN28 and OLIG2: (1) primitive neural (younger females with poorest survival), (2) oligoneural (older males with best survival), and (3) mesenchymal (older males with highest incidence of metastatic disease and intermedi-

FIGURE 150.5 Revised molecular classification of supratentorial embryonal tumors. Abbreviations: ATRT, atypical teratoid/rhabdoid tumor; BCL6, B-cell lymphoma 6; CNS, central nervous system; CPC, choroid plexus carcinomas; EFT, Ewing sarcoma family tumor; EPN, ependymoma; ETMR, embryonal tumor with multilayered rosettes; EWS, Ewing sarcoma; HDAC, histone deacetylase; HGG, high grade glioma or high-grade glioma; HGNET, high grade neuroepithelial tumor; IDH1, isocitrate dehydrogenase 1; IGF-IR, insulin like growth factor 1 receptor; MB, medulloblastoma; MNG, meningioma; NB, neuroblastoma; NOS, not otherwise specified; PARP1, poly(ADP-ribose) polymerase 1; PNET, primitive neuroectodermal tumor; PXA, pleomorphic xanthoastrocytoma; TRK, tropomyosin receptor kinase. ate survival). A high-level amplicon involving the C19MC identifies an aggressive subgroup of CNS PNET with distinct gene expression profiles and poor survival. ATRTs have monosomy or deletion of chromosome 22, and inactivating mutations of the hSNF5/INI-1 gene at 22q11.2 are considered fundamental to pathogenesis. Loss of chromosome 19 has been reported in AT/RT.

The resulting new classification of CNS embryonal tumors in WHO 2016 is shown in **Table 150.2**.

Astrocytes, Growth Factors, Tumor Suppressors, and Astrocytoma

Astrocytes develop later than neurons and continue to do so long after neurogenesis stops. Astrocytes retain the capacity for division throughout life and are more susceptible to transformation. Control over astrocyte proliferation and differentiation may be divided into two main categories: cell signaling and cell cycle arrest pathways. During glial development, precursor cells respond to growth factors such as epidermal growth factor (EGF) or platelet-derived growth factor (PDGF). Their receptors (EGF receptor [EGFR] and PDGF receptor [PDGFR]) are activated to stimulate tyrosine kinase activity and intracellular pathways that control proliferation and differentiation, programmed cell death, migration, cellular shape, and metabolism.

Amplification and mutation of EGFR are among the most common genetic abnormalities found in adult glioblastomas, particularly those arising de novo (as opposed to lesions progressing from fibrillary astrocytomas). These tumors contain ligands that may activate the receptor, stimulating a pathway that results in tumor progression. In addition, the receptor may be mutated to a constitutively activated form, unable to bind ligand but generating unregulated tyrosine kinase activity. Mice lacking EGFR have fewer GFAP-positive cells, and massive neuronal degeneration is attributed to a lack of trophic support from the missing glial cells. Amplification of EGFR is uncommon in pediatric high-grade astrocytomas, but significant differential expression of the EGFR/

TABLE 150.2 Classification of Central Nervous System (CNS) Embryonal Tumor Classification, WHO 2016[a]

Medulloblastoma, genetically defined
- Medulloblastoma, Wnt-activated
- Medulloblastoma, sonic hedgehog (SHH)-activated, TP53 mutant
- Medulloblastoma, SHH-activated, TP53 wild type
- Medulloblastoma, non-Wnt/non-SHH
  - Medulloblastoma, group 3
  - Medulloblastoma, group 4

Medulloblastoma, histologically defined - Medulloblastoma, classic - Medulloblastoma, desmoplastic/nodular - Medulloblastoma with extensive modularity - Medulloblastoma, large cell/anapestic
Medulloblastoma, not otherwise specified (NOS)
Embryonal tumor with multilayered rosettes (ETMR), C19MC-altered
ETMR, NOS
CNS neuroblastoma
CNS ganglioneuroblastoma
CNS embryonal tumor, NOS
CNS atypical teratoid/rhabdoid tumor
CNS embryonal tumor with rhabdoid features

FIGURE 150.6 Regulation of neuroglial cell proliferation. Neurofibromin operates as a tumor suppressor protein by accelerating the conversion of the RAS proto-oncogene from its active, guanosine triphosphate (GTP)-bound state to its inactive, guanosine diphosphate (GDP)-bound state. Loss of neurofibromin expression, as seen in neurofibromatosis type 1–associated gliomas, results in increased RAS-GTP levels and hyperactivation of downstream RAS signaling pathways, to result in increased cell growth. RAS activation following neurofibromin loss leads to high levels of mitogen-activated extracellular signal-regulated kinase (MEK)/extracellular-signal-regulated kinase (ERK) and phosphoinositide 3-kinase (PI3K)/protein kinase B (AKT)/mammalian target of rapamycin activity. Deregulated BRAF kinase activity leads to increased MEK/ERK signaling to result in high levels of mammalian target of rapamycin activation and increased cell growth. The *asterisks* denote the molecular targets for which clinically available pharmacologic inhibitors exist for the potential treatment of pilocytic astrocytomas in children. (Source: Chen Y-H, Gutmann DH. The molecular and cell biology of pediatric low-grade gliomas. *Oncogene*. 2014;33:2019-2026.)

FKBP12/HIF-2α growth- and angiogenesis-promoting pathway has been demonstrated. High PDGFR protein expression is associated with malignant histology in pediatric glioma but is not an independent prognostic factor. Attempts to block glioma progression through disruption of the EGFR pathway have led to development of drugs targeting EGFR or PDGFR.

Ras is a downstream effector of several growth factor receptors, signaling through both mitogenic and antiapoptotic pathways. It is under control of the *NF-1 gene* neurofibromin, and loss of function mutations in neurofibromin underlie the NF-1 syndrome, with predisposition to optic nerve glioma, astrocytoma, and glioblastoma. Neurofibromin functions as a Ras-guanosine triphosphatase-activating protein, but it had been unclear how Ras deregulation was involved in NF-1 pathogenesis. It has now been demonstrated that neurofibromin tightly regulates the mammalian target of rapamycin (mTOR) pathway. mTOR is a highly conserved serine/threonine protein kinase that regulates many steps in cell growth and proliferation, including ribosome biogenesis and protein translation. mTOR is constitutively activated in NF-1–deficient cells and tumors; aberrant mTOR activation depends on Ras and is mediated by the phosphorylation and inactivation of the tuberous sclerosis complex-2–encoded protein tuberin. Tumor cell lines from NF-1 patients are highly sensitive to the mTOR inhibitor rapamycin, which has therapeutic implications.

BRAF alterations (in particular tandem duplication and fusion KIAA1549-BRAF on chromosome 7q34) are now widely accepted as molecular markers for pilocytic astrocytoma, in particular for the differential diagnosis of supratentorial pediatric gliomas. Besides their diagnostic use, the evidence of mitogen activated protein kinase (MAPK) pathway–activating BRAF fusions and mutations in brain tumors has moreover drawn the attention of neurooncologists to the potential use of MEK1/2 and RAF inhibitors in the therapy of high- and low-grade gliomas (Fig. 150.6).

Molecular profiling of pediatric glioblastomas identifies at least two subsets. One group is associated with *Ras* and *Akt* pathway activation and exhibits increased expression of genes related to proliferation and a neural stem cell phenotype; this subset has very poor prognosis. A second group with better prognosis is not associated with activation of *Ras* and *Akt* pathways and may originate from astroglial progenitors. Both subsets show overexpression of Y-box-binding protein (YB-1), which may promote oncogenesis.

The tumor suppressor phosphatase with homology to tensin (PTEN) is mutated or lost in some pediatric high-grade astrocytomas, as in adult glioblastoma. PTEN is expressed throughout the embryo and is critical in CNS development. PTEN mutations are thought to cause Lhermitte-Duclos disease (dysplastic

gangliocytoma of the cerebellum) characterized by enlarged cerebellar folia, distorted cerebellar cortex, abnormally myelinated axon bundles, and dysplastic neurons. Conditional inactivation of the gene in the cerebellum of developing mice has generated a mammalian model of that disease. Loss of PTEN promotes astrocytic growth and survival because it would otherwise act as a repressor of antiapoptotic signaling pathways. PTEN is also thought to regulate astrocyte migration and invasion by effects on cell shape and movement. When PTEN is overexpressed, it inhibits tumor cell movement; conversely, reduction of PTEN activity promotes cell movement, invasiveness, and perhaps metastasis. Loss of PTEN has been associated with inferior survival in childhood gliomas. PTEN is a component gene in the mTOR pathway; immunohistochemical analysis of Lhermitte-Duclos disease lesions showed high levels of phospho-AKT and phospho-S6 in the large ganglionic cells, indicating activation of the PTEN/AKT/mTOR pathway and suggesting a central role for mTOR in Lhermitte-Duclos disease (LDD) pathogenesis as well as potential therapeutic intervention through pharmacologic inhibition of mTOR.

The tumor suppressors Rb protein and p53 are also regulators of cell survival and programmed cell death and are intimately involved with astrocytoma. Rb mutations in children lead to tumors in the retina, whereas mice null for Rb do not survive because of lethally abnormal patterns of neuronal development with pronounced CNS programmed cell death. Rb encodes a phosphoprotein important in cell cycle regulation, blocking transcription factors that promote proliferation. In the developing CNS, Rb is found in the ventricular zone where neuroblasts proliferate.

Rb is also involved in the regulation of apoptosis through interactions with the tumor suppressor p53, a transcription factor upregulated in response to cellular stress to facilitate arrest of the cell cycle for either DNA repair or cell death. Humans with the Li-Fraumeni syndrome lack p53 and show marked susceptibility to gliomas. p53 mutant mice develop tumors early in life.

Under conditions of Rb inactivation, many cells enter the cell cycle inappropriately and subsequently undergo apoptosis. However, Rb loss may synergize with the loss of apoptotic regulators, such as p53 to promote tumor formation. With the loss of Rb, transcription factors go unchecked, which then promotes cell proliferation. Loss of Rb might normally lead to apoptosis, but if p53 is also missing, apoptosis is impaired and tumorigenesis is enhanced. In fact, approximately 75% of adult glioblastomas show impaired apoptotic mechanisms and p53 pathway defects. Mutations in p53 were detected in one-third of childhood high-grade astrocytomas and nearly half overexpressed the p53 protein. This finding was strongly associated with adverse outcome.

Epigenetic mutations in histone and chromatin remodeling genes appear to be uniquely important in pediatric glioblastoma multiforme. Exome sequencing revealed H3.3 or H3.1 K27M mainly in brainstem HGA and K27M-H3.3 mainly in thalamic HGA (70%-80% of all glioblastoma in these locations). This mutated H3.3 (encoded by H3F3A) is inconsistently associated with ATRX mutations. G34R/V-H3.3 mutations occur mainly in cerebral hemispheric glioblastoma, similar to isocitrate dehydrogenase (IDH) mutations, which have a predilection for the frontal cortex. Both H3.3 mutations are significantly associated with ATRX mutations and TP53 mutations, mainly in older children and young adults with cerebral cortical glioblastoma. H3F3A mutations are also associated with alternative telomere lengthening. Increased TERC (telomerase RNA template) and human telomere reverse transcriptase (hTERT) mRNA (encoding telomerase catalytic component) have been associated with worse overall survival (OS) in children with non-brainstem high-grade glioma after controlling for tumor grade and extent of resection.

Investigation of molecular aberrations in DIPG has lagged because most cases are diagnosed clinically without pathologic confirmation. However, high-resolution single-nucleotide polymorphism–based DNA analysis of a series of DIPGs using postmortem samples revealed recurrent changes distinct from supratentorial high-grade astrocytomas, specifically expression (and gains) of platelet-derived growth factor receptor α (PDGFRA) and occasional low-level gains in poly(ADP-ribose) polymerase (PARP)-1. Mutations in H3F3A (encoding histone H3.3) or HIST1H3B (encoding histone H3.1) are common in DIPG. Whole-genome sequencing has identified three molecular subgroups of DIPG (H3 K27M, silent, and MYCN) and recurrent activating mutations involving the activin receptor gene ACVR1 in some cases.

H3.3K27M expression synergizes with p53 loss and PDGFRA activation in neural progenitor cells derived from human embryonic stem cells, resulting in neoplastic transformation. Genome-wide analyses indicate a resetting of the transformed precursors to a developmentally more primitive stem cell state, with evidence of major modifications of histone marks at several master regulator genes. Drug screening assays identified a compound targeting the protein menin as an inhibitor of tumor cell growth in vitro and in mice.

Another study of in vitro and xenograft models using postmortem DIPG tumor tissue found that the hedgehog signaling pathway is active in DIPG tumor cells, modulating self-renewal in neurosphere culture and promoting hypertrophy of the ventral pons. Thus, the Hedgehog pathway represents a potential therapeutic target in DIPG.

The anatomic location and age specificity of histone mutations and IDH mutations in childhood and adolescent high-grade astrocytoma are represented in Figure 150.7. More detailed information is summarized in Figure 150.8.

FIGURE 150.7 Neuroanatomic and age specificity of isocitrate dehydrogenase, K27M-H3.3 and G34R/V-H3.3 mutations in high-grade astrocytomas. Note: The size of the shape illustrating each mutation is approximately proportional to the percentage identified. (Source: Fontebasso AM, Liu X-Y, Sturm D, Jabado N. Chromatin remodeling defects in pediatric and young adult glioblastoma: a tale of a variant histone 3 tail. *Brain Pathol*, 2013;23:210-216.)

Ependymal Cells, RELA Fusions, and Ependymoma

Ependymomas arise from CSF-producing ependymal cells lining the ventricular system of the brain and spinal cord. Simian virus 40–related DNA sequences have been demonstrated in ependymomas and CPCs suggesting a viral etiology. Cytogenetic and molecular studies of childhood ependymomas have revealed isochromosome 1q as an early genetic event as well as rearrangements or deletions of chromosomes 6, 17, and 22. hTERT expression predicts tumor progression. Tumor-derived stem cells show a radial glia phenotype with gene expression patterns corresponding to radial glia cells from anatomically distinct compartments of the CNS.

Both supratentorial and infratentorial ependymomas are derived from radial glial cells, although supratentorial tumors may show neuronal differentiation. In the WHO 2016 classification, supratentorial ependymomas are divided into C11orf95-RELA positive (ST-EPN-RELA) or C11orf95-RELA negative/YAP1 fusion positive (ST-EPN-YAP1). ST-EPN-RELA tumors account for approximately 70% of supratentorial ependymomas in children. In ST-EPN-RELA tumors, the novel oncogenic fusion involving C11orf95 and RELA genes results from chromothripsis involving chromosome 11q13.1 and leads to aberrant activation of the nuclear factor-kappa B signaling pathway. ST-EPN-RELA tumors may also have homozygous deletion of CDKN2 or gain of chromosome 1q, both poor prognosis factors.

Infratentorial ependymomas are divided into two groups, A and B. Tumors in the first group (posterior fossa ependymoma A [PF-EPN-A]) exhibit a balanced genome with CpG island methylator phenotype; CpG methylation drives transcriptional silencing of differentiation genes. About 25% of PF-EPN-A tumors have gain of chromosome 1q, independently associated with poor prognosis. Tumors in the less common second group (posterior fossa ependymoma B [PF-EPN-B]) have a higher degree of genomic instability and cytogenetic aberrations but mainly involving gain or loss of whole chromosomes, without CpG island methylator phenotype; at least five subtypes are recognized.

A summary of clinical, histologic, and molecular characteristics of ependymomas across anatomic compartments is shown in Figure 150.9.

FIGURE 150.9 Ependymal tumors across central nervous system compartments, histopathologic grades, and age groups. (Source: Pajtler KW, Witt H, Sill M, et al. Molecular classification of ependymal tumors across all CNS compartments, histopathological grades, and age groups. *Cancer Cell*. 2015;27:728-743.)

Integrated Classification of Central Nervous System Tumors

Pathologic diagnosis is based on the WHO classification, which distinguishes astrocytic tumors, oligodendroglial tumors and mixed gliomas, ependymal tumors, choroid plexus tumors, and neuronal and mixed neuronal–glial tumors. Among entities newly incorporated in the 2007 revised classification were angiocentric glioma, papillary glioneuronal tumor, rosette-forming glioneuronal tumor of the fourth ventricle, papillary tumor of the pineal region, pituicytoma, and spindle cell oncocytoma of the adenohypophysis. Newly described histologic variants of pediatric tumors included pilomyxoid astrocytoma, anaplastic medulloblastoma, and medulloblastoma with extensive nodularity. In addition, the rhabdoid tumor predisposition syndrome was added to the list of familial cancer syndromes.

Some childhood brain tumors, such as supratentorial astrocytomas, have been difficult to characterize in the WHO classification. A proposed pediatric classification divides tumors into glial, mixed glial–neuronal, neural, embryonal, and pineal categories. Glial tumors include astrocytoma, ependymoma, oligodendroglioma, and choroid plexus tumor. Mixed glial–neuronal tumors include ganglioglioma and subependymal giant cell tumor. Neural tumors include gangliocytoma. Embryonal tumors are PNET, ATRT, and medulloepithelioma. Pineal tumors are represented by pineocytoma.

The 2016 revision of the WHO classification features many changes that are relevant to clinicians and researchers. The 2016 CNS WHO introduces diagnostic terms that "integrate" histologic and molecular information and suggests presenting diagnoses in a four-layered reporting format. In addition, it uses a "not otherwise specified" designation to identify diagnostic categories that are not precisely defined. A better understanding of the biology of specific entities led to changes in tumor nosology, such as diffuse gliomas based on IDH gene status, and diffuse midline gliomas H3 H27M mutant (Table 150.3).

For embryonal tumors and related entities, molecular subgroups were identified, including medulloblastoma Wnt-activated and SHH-activated, ETMR C19MC-altered, and RELA fusion–positive ependymomas. There will likely be additional practical advances that emerge over the next few years. A new initiative entitled Consortium to Inform Molecular and Practical Approaches to CNS Tumor Taxonomy will formulate recommendations between WHO updates.

TABLE 150.3 2016 World Health Organization Classification and Histologic Grade of Astrocytic Tumors[a]

Tumor Type	Grade	Common Locations
Diffuse Astrocytic Tumors		
Diffuse astrocytoma, IDH mutant Diffuse astrocytoma, IDH wild type	II	Cerebrum
Anaplastic astrocytoma, IDH mutant Anaplastic astrocytoma, IDH wild type	III	Cerebrum
Glioblastoma, IDH mutant Glioblastoma, IDH wild type	IV	Cerebrum
Diffuse midline glioma, H3K27M mutant	IV	Thalamus, brainstem
Other Astrocytic Tumors		
Pilocytic astrocytoma	I	Optic nerve, chiasm/hypothalamus Thalamus, basal ganglia Cerebral hemispheres Cerebellum, brainstem, spinal cord
Pilomyxoid astrocytoma	Uncertain	Third ventricle, midbrain
Pleomorphic xanthoastrocytoma	II	Temporal lobe
Anaplastic pleomorphic xanthoastrocytoma	III	Temporal lobe
Subependymal giant cell astrocytoma	I	Ventricle
Other Gliomas		
Angiocentric glioma	I	Cerebrum
Chordoid glioma of the third ventricle	II	Third ventricle
Astroblastoma	Uncertain	Cerebrum

Abbreviation: IDH, isocitrate dehydrogenase.
[a]Source: Louis DN, Perry A, Reifenberger G, et al. The 2016 World Health Organization classification of tumors of the central nervous system: a summary. *Acta Neuropathol*. 2016;131:803-820.

Pathologic diagnosis is greatly facilitated by immunohistochemical staining for specific markers such as GFAP in glial tumors, epithelial membrane antigen in ependymoma, and synaptophysin or neurofilament in medulloblastoma and gangliogliomas. Additional serum and immunohistochemical markers include α-fetoprotein (AFP) and human chorionic gonadotropin (HCG) for germ cell tumors, S100 for neural tumors, smooth muscle actin for AT/RT, and cytokeratin for CPC. An important trend in tumor pathology is the application of cytogenetic and DNA approaches. Examples are isochromosome 17q in medulloblastoma, chromosome 1p and 19q deletions in oligodendroglioma, and monosomy or deletion of chromosome 22 (hSNF/INI-1 locus) in ATRT. Molecular characterization is now incorporated into the integrated final diagnosis, and tumor tissue immunostaining is now available for certain mutations such as H3 K27M and BRAF V600E. Moreover, histone H3 mutations have been shown to be detectable in CSF-derived tumor DNA from children with diffuse midline glioma. A consensus recommendation is that next generation sequencing should be routinely included in the workup of most pediatric gliomas.

CLINICAL FEATURES

Symptoms

Children with brain tumors often present with symptoms and signs of increased intracranial pressure (ICP). Many pediatric tumors arise in ventricular or periventricular locations (including medulloblastoma, ependymoma, and choroid plexus tumors). Tumor-associated mass effect may result in obstruction of normal CSF pathways, with ventriculomegaly. Characteristic signs are headache, vomiting, and diplopia, but the onset may be gradual and nonfocal. Fatigue, personality change, or worsening school performance may be described. Symptoms in infants are nonspecific and include irritability, anorexia, persistent vomiting, and developmental delay or regression, with macrocephaly and seemingly forced-downward deviation of the eyes ("sunset sign"). Beyond infancy, symptoms tend to be more specific to anatomic location (**Fig. 150.10**). The median duration of symptoms before diagnosis was 2 months in two series; only one-third of the patients were diagnosed in the first month after onset of symptoms, but diagnostic delay is less important than tumor aggressiveness in determining survival outcome. Persistent vomiting, recurrent headache (awakening the child from sleep), neurologic findings (ataxia, head tilt, weakness, vision loss, papilledema), endocrine disturbance (growth deceleration, diabetes insipidus, precocious puberty), and stigmata of neurofibromatosis should all prompt evaluation for the presence of a CNS tumor.

Symptoms of CNS tumors generally correlate with tumor location (see **Fig. 150.10**). Supratentorial tumors, which predominate in infants and toddlers and also occur in older children, cause headache, limb weakness, sensory loss, and occasionally seizures, deteriorating school performance, or personality change. Seizures are a presenting symptom in 10% to 15% of children with brain tumors and may be generalized, focal motor, or psychomotor; electroencephalogram is almost always abnormal. Most tumors associated with seizures are located in the temporal lobe; frontal lobe tumors more often affect personality and movement. The incidence of underlying neoplasm in children with intractable epilepsy approaches 20%, and the increased risk

FIGURE 150.10 Symptoms of central nervous system tumors according to location. Abbreviation: ICP, intracranial pressure. (Source: Wilne S, Collier J, Kennedy C, Koller K, Grundy R, Walker D. Presentation of childhood CNS tumours: a systematic review and meta-analysis. *Lancet Oncol.* 2007;8:685-695.)

of having a brain tumor persists even 10 or more years after a clinical diagnosis of epilepsy.

Parietal lobe tumors affect reading ability and awareness of contralateral extremities (hemineglect). Occipital lobe tumors cause visual field disturbance and occasionally hallucinations. Suprasellar lesions may cause both visual field defects and endocrine dysfunction. The Parinaud syndrome (upgaze paresis and mild pupil dilatation with better reaction to accommodation than light, retraction or convergence nystagmus, and lid retraction) is found in pineal region tumors.

Infratentorial tumors, which predominate from ages 4 to 11 years, typically cause headache, vomiting, diplopia, and imbalance. Bilateral sixth cranial nerve palsy is a frequent sign of increased ICP. Brainstem tumors cause facial and extraocular muscle palsies, ataxia, and hemiparesis. Leptomeningeal spread occurs at diagnosis or recurrence in up to 15% of children with CNS tumors (more often in medulloblastoma or occasionally ependymoma) and may be asymptomatic or may cause pain, irritability, weakness, or bowel and bladder dysfunction.

Children with confirmed diagnosis of NF-1 have approximately 15% to 20% incidence of optic pathway gliomas, and require surveillance ophthalmologic examinations at least annually. Most optic pathway gliomas develop by age 6 years, when reliable ophthalmologic evaluation may be difficult, but MRI screening remains controversial. Indications for neuroimaging include vision change, new or worsening symptoms, and accelerated growth or precocious puberty. MRI screening of unselected NF-1 patients detected optic pathway gliomas in 18% at a median age of 3 years, of whom 15% had progression requiring therapy, particularly those with schismatic and postchiasmatic tumors. Patients with vision deficits at diagnosis were more likely to experience visual decline despite therapy when compared to presymptomatic

patients diagnosed by MRI. Children with negative brain and orbital MRI screening at age 15 months or later did not develop symptomatic optic pathway gliomas.

Brain tumors may also be discovered as incidental findings in children undergoing imaging for other reasons, without specific CNS signs. When radiologic characteristics suggest the possibility of a low-grade tumor, the accepted approach is interval follow-up. Further intervention may be required in about 10% of cases.

Diagnosis

MRI is the preferred imaging modality for evaluation of children with symptoms suggestive of brain tumor (eg, persistent headache of recent onset, morning vomiting) and abnormal signs on neurologic examination (head tilt, ataxia) or other clinical predictors of brain tumor (diabetes insipidus). CT may be the initial evaluation (especially if hydrocephalus or intracranial hemorrhage is suspected), but compared with CT, MRI is more sensitive (especially for nonenhancing, infiltrative tumors and leptomeningeal involvement), may generate images in any plane (eg, axial, coronal, sagittal), and is not compromised in the posterior fossa by bone artifact. Brain tumors are typically hypo- or isointense on T1-weighted imaging and hyperintense on T2-weighted imaging. Contrast enhancement is a feature of malignant tumors, reflecting blood-brain barrier disruption. Perfusion and diffusion sequences may also be useful in assessing tumor aggressiveness. Magnetic resonance spectroscopy (MRS) can provide additional information; for example, compared to benign tumors or normal brain, malignant tumors have increased choline peaks (reflecting increased membrane turnover) and decreased *N*-acetylaspartate (absence of functional neurons). MRI is repeated postoperatively to confirm extent of tumor resection, although it may be difficult to distinguish tumor from surrounding edema or residual tumor from postoperative changes; for these reasons, postoperative studies should be obtained within 48 hours of surgery.

MRI of the spine has replaced myelography as the standard procedure for evaluation of spinal cord tumors, drop metastases, and leptomeningeal disease. Spine MRI is required in cases of medulloblastoma, ependymoma, CPC, AT/RT, and pineal region tumors and should be obtained preoperatively if one of these diagnoses is suspected. Lumbar puncture for CSF cytology and tumor markers should also be done in children with these diagnoses. Recommended baseline and surveillance studies, based on tumor aggressiveness and patterns of recurrence, are shown in Table 150.4.

Guidelines for brain tumor assessment (based on evaluation of adult high grade gliomas) were updated in 2010 by the Response Assessment in Neuro-Oncology Working Group, replacing the previously used Macdonald criteria, and incorporating T2 and fluid-attenuated inversion recover (FLAIR) sequences to assess nonenhancing tumor growth. This partly addressed the issue of treatment-related tumor pseudoprogression in the first 12 weeks postradiation therapy, typically with new T2/FLAIR intensity within the high-dose treatment region (80% isodose line). Application of Response Assessment in Neuro-Oncology Criteria to pediatric neuro-radiology must take into account brain development, tumor heterogeneity, and variable blood-brain barrier integrity. The Response Assessment in Pediatric Neuro-Oncology Working Group is addressing these issues.

Treatment responses are determined by change in tumor size on MRI based on the most reproducible measurements from T2/FLAIR-weighted or postcontrast T1-weighted images, whichever gives the best estimate of tumor size. Measurements of the longest tumor dimension and its perpendicular should be recorded for all target lesions (up to 5) and any new lesions. In assessing response, lesions less than twice the combined thickness of the image slice and interslice gap are discounted, and cystic/necrotic elements and/or leptomeningeal disease are generally

TABLE 150.4 Baseline and Surveillance Studies in Children With Central Nervous System Tumors[a]

Diagnosis	Baseline Evaluation	Surveillance (Months From End of Treatment)

[b]If residual or dissemination.

[c]If symptoms.

not measured. Enlargement or reduction of existing lesions should correlate with increase or decrease in two-dimensional measurement, but increased enhancement on T1 without increase in disease bulk on T2/FLAIR is not considered tumor progression, and decreased enhancement without decreased bulk on T2/FLAIR may represent altered contrast permeability rather than regression. Thus, complete or partial response requires disappearance or greater than 50% reduction of all target lesions, respectively, whereas 25% increase or the appearance of new lesions or newly positive CSF cytology indicates progressive disease. Imaging may be supplemented by positron emission tomography (PET), which characterizes metabolic abnormalities that distinguish high grade from low grade and residual or recurrent tumor from cerebral necrosis. Thallium 201 single-photon emission CT is sensitive for recurrent tumors, although MRS offers similar capability and is more widely available.

TREATMENT

Surgery

The mainstay of therapy for childhood brain tumors is surgery, which may be curative by itself in congenital, benign, and low-grade tumors. For example, pilocytic astrocytoma arising in the cerebellum can be completely or nearly completely resected in nearly all patients, and cerebral hemispheric low-grade tumors are often completely resectable. Gross total resection (no visible tumor at completion of surgery) or radical subtotal resection (95%-99% tumor removal) is generally attempted in malignant tumors and contributes to the cure rates of ependymoma and medulloblastoma (Fig. 150.11). Resection of a high-grade astrocytoma improves the otherwise guarded prognosis. Aggressive resection of low-grade astrocytomas in midline structures (hypothalamus, thalamus, brainstem, and spinal cord) can provide long-term disease control but with risk of neurologic sequelae.

The introduction of the operating microscope and ultrasonic aspirator has improved both the safety and effectiveness of surgery. Adoption of intraoperative MRI can improve the rate of tumor resection and may alter surgical strategy. The extent of resection should be confirmed by postoperative MRI. Radical resection is generally not attempted for infiltrative lesions deep in the thalamus, intrinsic to the brainstem, or in functionally eloquent areas; in these sites, surgery is typically limited to open or closed biopsy (<1% resection) or partial or subtotal resection (10%-49% and 50%-95% tumor removal, respectively). Advanced neuroimaging techniques, which may be useful for mapping eloquent regions include magnetoencephalography, diffusion tensor imaging, and functional MRI. Multiple biopsies may be useful in lesions appearing heterogeneous on MRI when major resection is not attempted. Some lesions can be approached using minimally invasive procedures, such as endoscopic third ventriculostomy. Stereotactic (eg, CT- or MRI-guided) techniques are used for biopsy or subtotal resection in difficult-to-reach areas such as the basal ganglia. However, even a 99% resection of a lesion that is 10 cm^3 in size will leave 10^8 tumor cells behind, and additional postoperative treatment will be necessary to prevent the lesion from regrowing.

Some lesions respond well to radiotherapy and/or chemotherapy, such that confirmatory biopsy is sufficient. For example, pineal region germinoma is highly sensitive to both radiation and chemotherapy, so radical resection should not be attempted, whereas choriocarcinoma (recognized by serum and CSF HCG elevation) and pineoblastoma require more substantial resection.

FIGURE 150.11 Tumor evaluation by magnetic resonance imaging (MRI). Abbreviations: FLAIR, fluid-attenuated inversion recovery; GPD, greatest perpendicular diameter; LD, longest diameter; PCD, product of cross-sectional enhancing diameters; rCBV, relative cerebral blood volume.

In addition to establishing a tissue diagnosis, surgery may be necessary for relief of obstructive hydrocephalus. With temporary placement of an external drain or endoscopic third ventriculostomy, followed by tumor resection, it may be possible to avoid the need for a permanent ventriculoperitoneal shunt in most patients.

Operative mortality is generally no more than 1%, but morbidity varies according to the site and extent of surgery and the condition of the child. A unique and increasingly recognized complication of midline posterior fossa tumor resection is the cerebellar mutism syndrome, consisting of diminished speech progressing to mutism, emotional lability, hypotonia, and ataxia. In two prospective trials for standard and high-risk medulloblastoma, cerebellar mutism was reported in 24% of children. In both cohorts, brainstem invasion by tumor was the only predictive feature. At 1 year from diagnosis, nonmotor speech/language deficits, neurocognitive deficits, and/or ataxia persisted in a substantial proportion of patients.

Surgery is facilitated by real-time neuronavigation, in which preoperative imaging is updated during surgery to account for anatomic shifts in the brain (Fig. 150.12). Surgery may also be facilitated by intraoperative monitoring of sensory and other evoked potentials.

Adjunctive measures include the use of corticosteroids, which counteract tumor edema and are often used in the perioperative period but should be tapered within 1 to 2 weeks, if possible. Patients undergoing surgery for supratentorial tumors are placed on anticonvulsants if they have had seizures or if the surgical approach is likely to cause seizures. Prophylactic anticonvulsants are generally continued for 1 week to 12 months.

Patients may be referred for second look surgery following subtotal resection and interim chemotherapy. This approach is incorporated into protocols for newly diagnosed ependymoma. Patients with symptomatic recurrence are also referred for reoperation, particularly with the possibility of clonal evolution (as in medulloblastoma) or to provide tissue for molecular testing to identify potential therapeutic targets.

Radiation Therapy

Radiation therapy is used for nearly all malignant CNS tumors and for some low-grade lesions as well, particularly at recurrence or progression. Based on standard x-ray (photon) therapy, doses typically administered to achieve local control range from 45 to 55 Gy, in divided fractions of 150 to 200 cGy, to the tumor as localized on MRI plus 1- to 2-cm margin. Higher doses may be given, often in smaller twice-daily doses (eg, hyperfractionated technique), but with high total doses, there is increased risk of injuring normal brain tissue. The volume irradiated depends on tumor histology and may include an involved field or whole brain and spine. Presymptomatic craniospinal irradiation is almost always given for medulloblastoma because of its propensity to disseminate throughout the neuraxis. Doses of 36 Gy have been used conventionally, but lower doses (23.4 Gy and possibly 18 Gy) are adequate in standard-risk patients if supplemented with adjuvant chemotherapy.

Newer radiotherapy techniques may increase the effective tumor dose and limit toxicity to the surrounding brain. *Three-dimensional conformal radiation therapy* allows tailoring of treatment to the actual tumor volume rather than arbitrary compartments such as the whole posterior fossa. *Stereotactic irradiation* techniques with arc photons, in conjunction with rigid head fixation systems, permit single high-dose delivery (eg, radiosurgery), which may be useful for management of recurrent lesions in previously irradiated patients. *Intensity-modulated radiation therapy* uses combinations of variable intensity fields from different beam directions to maximize tumor dose while minimizing dose to adjacent normal tissues. *Proton therapy* takes advantage of the superior physical properties of protons compared to

FIGURE 150.12 Intraoperative panel of images in 13-year-old male with left occipital pilocytic astrocytoma. This child was operated upon using frameless stereotaxy and intraoperative neuronavigation to ensure complete removal of his lesion. (Source: Nejat F, El Khashab M, Rutka JT. Initial management of childhood brain tumors: neurosurgical considerations. *J Child Neurol*. 2008;23:1136-1148.)

photons, with limited penetration of particles beyond the tumor target, less tissue scatter, and little lateral dispersion. Early applications of proton therapy included ocular melanoma and skull base tumors, but the possibility of comparable tumor control with substantially decreased dose to adjacent normal tissues makes the technique potentially advantageous for many pediatric indications. *Interstitial radioactive implants (brachytherapy)* may be appropriate in some cases. Use of *radiation sensitizers*, including chemotherapy agents (carboplatin, capecitabine, tipifarnib) and gadolinium derivatives, is currently under study.

Acute side effects of radiation therapy include headache, nausea, alopecia, skin hyperpigmentation and desquamation, and a transient "somnolence syndrome," occurring 4 to 8 weeks after treatment. Radiation-associated imaging changes such as pseudoprogression and radiation necrosis must be distinguished from true tumor progression with convincing 25% volume increase and/or appearance of disease in previously uninvolved locations. Radiation therapy to large volumes is problematic in infants and toddlers because of increased neurocognitive sequelae. Dose-intensive chemotherapy may be used to defer irradiation, or involved field treatment with supplemental chemotherapy may be substituted for whole-brain irradiation (as in medulloblastoma). Radiation therapy is deferred in patients with NF-1 in favor of chemotherapy because these patients may have increased susceptibility to radiation toxicity and second malignancies.

Chemotherapy

Chemotherapy is used as an adjunct to radiotherapy and as postradiation maintenance therapy in medulloblastoma and high-grade astrocytomas as neoadjuvant therapy in chemotherapy-sensitive tumors (eg, CNS germ cell tumors), as primary postsurgical treatment in infants, and in recurrent tumors. Effective agents include the nitrosoureas (eg, carmustine, lomustine), vincristine, cisplatin, carboplatin, etoposide, and cyclophosphamide. Temozolomide appears promising, although response rates in phase II trials have been relatively low. Chemotherapy is generally given systemically and in combination because of complementary mechanisms of action of different agents and to subvert potential tumor resistance. The effectiveness of systemically administered chemotherapy is limited by the blood-brain barrier. Regional delivery of drugs (eg, intra-arterial, intrathecal, intratumor) potentially circumvents this problem, and responses to intra-arterial carboplatin- or methotrexate-based chemotherapy with osmotic blood-brain barrier disruption are reported for germ cell tumors and primary CNS lymphoma. The dose intensity of conventional, systemic chemotherapy may be increased with the use of hematopoietic growth factors, which shorten the period of myelosuppression and permit the use of higher doses or shorter intervals between treatments. A related approach is the use of extremely high doses of chemotherapy, supported by autologous hematopoietic stem cell rescue, and this approach has been used for chemotherapy-sensitive recurrent tumors or as an intensive consolidation therapy for infants.

The role of adjuvant cisplatin-based chemotherapy following radiation is well established for childhood medulloblastoma and pineoblastoma. For standard-risk medulloblastoma, use of chemotherapy permits reduction in the dose of radiotherapy. Dose-intensive cyclophosphamide-based chemotherapy has been used following radiation therapy for standard- and high-risk medulloblastoma with the goal of reducing exposure to cisplatin. For high-grade astrocytomas, temozolomide is used routinely with and following radiation therapy, as in adults. Preirradiation chemotherapy is being tested in CNS germ cell tumors ependymoma but has been generally ineffective in medulloblastoma and high-grade astrocytomas, including brainstem tumors, presumably because of delaying definitive radiation therapy.

In very young patients (infants and toddlers younger than age 3-4 y) with malignant brain tumors, dose-intensive chemotherapy is commonly used postoperatively with the goal of deferring or avoiding radiation therapy. This approach appears effective in medulloblastoma and AT/RT. Intrathecal therapy (intraventricular and intralumbar methotrexate) has also been advocated for medulloblastoma in a protocol designed to avoid radiation therapy.

Chemotherapy is commonly used for recurrent CNS tumors, and patients may receive additional irradiation as well. High-dose chemotherapy with stem cell rescue may offer effective salvage therapy for recurrent medulloblastoma at least when combined with radiation therapy in younger previously unirradiated patients. Established and newer chemotherapy agents can be tested against panels of childhood brain tumor xenografts. Doses of certain chemotherapy agents such as irinotecan may require adjustment if patients are also receiving hepatic enzyme–inducing anticonvulsant drugs such as phenytoin, phenobarbital, carbamazepine, and Mysoline (primidone).

Biologic agents in clinical trials for recurrent CNS tumors include differentiation agents (retinoic acid), agents targeting tumor growth factor receptors (erlotinib, gefitinib, imatinib, lapatinib), farnesyltransferase inhibitors (tipifarnib), agents interfering with angiogenesis (bevacizumab, cilengitide, lenalidomide), histone deacetylase inhibitors (suberoylanilide hydroxamic acid, valproic acid), heat shock protein inhibitors (17-allylaminogeldanamycin), and DNA repair enzyme inhibitors (O^6-benzylguanine).

With detailed identification of gene mutations and fusions by DNA tumor whole exome sequencing and RNA methylation array, it is possible to tailor "targeted" therapy to entire molecular pathways, taking into account downstream targets. For example, vemurafenib targets *BRAF V600E* mutation in ganglioglioma, but not *KIAA1549-BRAF* fusion, which is more frequent in pilocytic astrocytoma; in the latter situation, an alternative treatment strategy is downstream inhibition of MEK by trametinib.

Immunotherapy would be an attractive option for treatment of pediatric CNS tumors but remains an elusive goal. Convection-enhanced delivery of chemotherapy and immunotoxin conjugates are currently being evaluated. Certain glioma-associated antigens are overexpressed on pediatric brainstem and nonbrainstem gliomas and could be suitable targets for vaccine strategies.

SPECIFIC TYPES OF PEDIATRIC CENTRAL NERVOUS SYSTEM TUMORS

Congenital Tumors

Craniopharyngioma

Craniopharyngioma originates from embryonic tissue rests located in the Rathke pouch, which later forms the anterior pituitary gland. Craniopharyngioma may appear clinically at any age, even later adulthood, and constitutes 6% to 10% of intracranial tumors in children. Craniopharyngiomas vary from small,

FIGURE 150.13 Axial (A) and sagittal (B) magnetic resonance imaging of a craniopharyngioma.

well-circumscribed, solid nodules to huge, multilocular cysts invading the sella turcica. The cysts are filled with turbid fluid that may contain cholesterol crystals. Clinical manifestations include short stature, hypothyroidism, and diabetes insipidus, with vision loss and signs of increased ICP. CT is useful for demonstrating calcification and bony expansion of the sella, but MRI is preferred for better definition of the relationship of the tumor to neighboring vessels, optic chiasm and nerves, and the hypothalamus (Fig. 150.13).

Craniopharyngiomas are histologically benign and may be categorized as mucoid epithelial cysts, squamous epitheliomas, or adamantinomas; the latter is the most frequent in children. Activating β-catenin (CTNNB1) gene mutations are found in most adamantinomatous tumors. Total surgical removal may be difficult because the tumor can invade the hypothalamus or third ventricle and adhere to optic nerves or blood vessels. A conservative approach is to drain the cyst and resect nonadherent tumor and then administer radiation therapy to the involved area. For children younger than 3 years, it may be preferable to defer resection by implanting an intracystic catheter with subcutaneous reservoir for serial cyst fluid drainage. Definitive treatment options are complete resection or subtotal resection with radiation therapy. In addition to the standard transsphenoidal approach for small tumors, there is renewed interest in the endonasal approach with endoscopic visualization as an alternative to craniotomy. Recurrence rates at 5 years after complete resection or subtotal resection with irradiation are similar in pediatric series (10%-20%). Radical surgery is likely to be accompanied by panhypopituitarism, necessitating lifelong hormonal replacement therapy, whereas irradiation has lesser hormonal sequelae but causes cognitive deficits, especially in younger children. Focused treatment by stereotactic radiosurgery (eg, Gamma Knife), especially at recurrence, may be advantageous in this regard. Interferon alfa-2a and pegylated interferon alfa-2b have been used in recurrent craniopharyngiomas.

The other type of pituitary tumor is adenoma, which is rare in childhood but increasingly frequent in adolescents and common in adults (up to 5% incidence in autopsy series). Adenomas may be associated with Cushing disease, hyperprolactinemia, and acromegaly. Functioning adenomas in childhood are most often ACTH-producing, whereas prolactinomas are most frequent in adolescents. Pituitary adenomas are usually sporadic but may be manifestations of genetic conditions such as multiple endocrine neoplasia type 1, Carney complex, familial isolated pituitary adenoma, and McCune-Albright syndrome. Initial treatment is with dopamine agonists such as bromocriptine, whereas surgery is reserved for symptomatic tumors causing hydrocephalus or vision loss. Surgery is indicated for asymptomatic arachnoid cysts causing obstructive hydrocephalus or seizures; options include cystectomy, fenestration, or cyst-peritoneal shunting.

Epidermoid Cysts

Epidermoid cysts (cholesteatomas) account for about 2% of all intracranial tumors. They arise within skull tables or adjacent to the dura usually in the suprasellar region, skull base, brainstem or cerebellopontine angle, or within a ventricle. They arise from epithelial cells retained during neural tube closure, have a pearly appearance, and may contain cyst fluid with cholesterol crystals. Clinical onset is usually in young adulthood, with hearing loss, hemifacial spasm, or trigeminal neuralgia. MRI demonstrates a lesion with low T1- and high T2-weighted signal intensity (Fig. 150.14); involvement of multiple cranial nerves and the internal carotid artery is common. Treatment is surgical resection with radical removal of the tumor capsule.

Dermoid tumors are also cystic, and sebaceous gland secretions impart a dark yellow color to the cyst fluid. Intracranial dermoids are associated with Goldenhar syndrome (ie, oculo-auriculo-vertebral dysplasia). Treatment is surgical resection. Epidermoid and dermoid cysts occasionally undergo malignant transformation into squamous cell carcinoma.

Arachnoid cysts are also in the differential of extra-axial cystic lesions. Arachnoid cysts result from focally impaired CSF flow and cystic dilatation of subarachnoid spaces, typically in the sylvian fissure, presenting with headache and occasionally seizures. MRI can be helpful in distinguishing arachnoid cysts from epidermoid cysts. CSF signal is seen in both; gut epidermoid cysts show hyperintense FLAIR signal and reduced diffusion on diffusion-weighted imaging, whereas arachnoid cysts have low signal on FLAIR and diffusion-weighted imaging (unless containing proteinaceous fluid or blood). A large cisterns magna (either a normal variant or associated with Dandy-Walker

FIGURE 150.14 Sagittal **(A)** and axial **(B)** magnetic resonance imaging of a pontomedullary epidermoid cyst.

syndrome) may resemble an arachnoid cyst but does not cause mass effect on the cerebellum and vermis. Surgery is indicated for asymptomatic arachnoid cysts causing obstructive hydrocephalus or seizures; options include cystectomy, fenestration, or cyst-peritoneal shunting.

Teratoma and Chordoma

Teratomas are composed of cells originating from at least two and usually all three embryonic layers: ectoderm, mesoderm, and endoderm. Extragonadal teratomas occur in infants as sacrococcygeal tumors. Intracranial teratomas have also been reported in infants, usually supratentorial or intraventricular, presenting with macrocephaly. Posterior fossa immature teratoma in an infant with trisomy 21 has been reported. Although rare, teratoma is the most frequently intracranial tumor encountered at birth and may be detected on fetal ultrasound. Infant MRI reveals a large cystic and solid contrast-enhancing mass, which may contain fat and calcifications. Extra-axial teratomas may arise in the pineal or suprasellar region in older children. Teratomas may be classified as mature, immature, or mature with malignant transformation. Treatment is surgical resection, but prognosis for immature and transformed teratomas is guarded, and adjuvant chemotherapy may be considered.

Chordomas develop from remnants of the embryonic notochord. Half are in the sacrococcygeal region, one-third at the sphenoid-occipital junction, and the remainder elsewhere along the spinal column. They are rare, accounting for less than 1% of CNS tumors, and usually remain asymptomatic until adulthood. These tumors are locally invasive and cause vision loss or cranial nerve dysfunction. They may invade the nasopharynx or intracranial sinuses and may extend into the neck causing torticollis. Childhood chordoma can be associated with tuberous sclerosis.

Chordomas have a smooth, nodular surface that resembles cartilage; the characteristic histologic feature is the presence of large masses of physaliferous cells and round or polygonal cells arranged in cords and having large cytoplasmic vacuoles containing mucin. Chordomas grow slowly but may recur after excision. A malignant variant is distinguished by mitotic spindle cells and may metastasize to the lung. Chordoma should be suspected in a patient presenting with multiple cranial nerve palsies or erosion of the skull base. Treatment is surgical resection, although gross total resection is rarely achieved. Radiation therapy may be used postoperatively or at recurrence. Proton radiotherapy is advocated because it may confer effective local control and possibly better cosmetic outcome than with conventional irradiation. There has been no defined role for chemotherapy in chordoma, but loss of SMARCB1/INI1 protein in poorly differentiated chordomas has been reported, associated not with point mutations but with SMARCB1/INI1 gene deletions instead, potentially targetable by the EZH inhibitor tazemetostat.

Choroid Plexus Tumors

Choroid plexus tumors are rare congenital tumors arising in the choroid plexus of the lateral or fourth ventricles. They may cause symptoms shortly after birth, and most are diagnosed before age 2 years. The first manifestation is likely to be macrocephaly resulting from hydrocephalus, with bulging fontanelle and split sutures noted in infants. Excess CSF production arising from the tumor may approach 2,000 mL/d.

The majority are choroid plexus papillomas (CPPs; WHO grade I), slowly growing hamartomatous lesions that extend into a ventricle and tend not to be invasive. CPPs may arise in Aicardi syndrome, Down syndrome, von Hippel-Lindau disease, and NF-2. Papillomas are often calcified on CT scan and enhance with contrast; they must be distinguished in the infant age group from ependymomas, which lack calcification. Atypical papillomas (WHO grade II) have a higher growth fraction (mitotic rate by MIB-1 >2%). Total excision of localized lesions may be curative and stops the excessive CSF production, but malignant transformation of incompletely resected papillomas has been reported.

CPCs (WHO grade III) typically arise in a lateral ventricle and invade the brain parenchyma with development of hydrocephalus (Fig. 150.15). Hydrocephalus may result from obstruction of normal CSF flow, overproduction of CSF by the tumor itself, local expansion of the ventricles, or spontaneous hemorrhage. CPCs are more heterogeneous than CPPs on imaging due to focal necrosis and surrounding vasogenic edema; in nearly half of cases, there is dissemination in the leptomeninges.

According to the 2016 WHO criteria, CPC must harbor at least four of the five following characteristics: elevated mitotic activity (generally >5 mitoses per 10 HPF), hypercellularity,

FIGURE 150.15 Magnetic resonance imaging of a choroid plexus carcinoma of the lateral ventricle with parenchymal invasion.

nuclear pleomorphism, solid growth with sheets of tumor cells, and necrosis. Extensive invasion into the surrounding brain parenchyma is a frequent finding.

Immunohistochemistry of CPP and CPC shows positivity for pancytokeratin, with variable positivity for S-100, GFAP, and synaptophysin. E-cadherin is positive in most choroid plexus tumors, distinguishing them from ependymomas, which are typically negative. Platelet-derived growth factor (PDGF) receptors may be overexpressed or amplified in some CPCs. CPC may be a manifestation of Li-Fraumeni syndrome or rhabdoid predisposition syndrome, and evidence should be sought for germ line mutation in TP53 or hSNF5/INI1/SMARCB1, respectively. Cells with a rhabdoid morphology are not uncommon in CPCs, and such tumors need to be differentiated from AT/RT, for example, by p53 positivity and retained nuclear INI-1 (BAF-47) reactivity. Differences in gene copy number, gene expression, and DNA methylation signatures distinguish CPCs from CPPs and atypical CPP; however, molecular similarities among the papillomas suggest that these two histologic subgroups are indeed a single molecular entity. A greater number of copies of mutated TP53 were significantly associated with increased tumor aggressiveness and a worse survival outcome in CPCs.

CPPs may be cured by surgery alone, with 5-year survival of 80% to 100% following gross total resection and 60% to 70% following subtotal resection. Atypical CPP has increased risk of local recurrence, and, in the CPT-SIOP-2000 study, infants with incompletely resected atypical CPP were given adjuvant chemotherapy with 97% survival at 5 years.

CPCs behave aggressively with a tendency for leptomeningeal dissemination and local recurrence. Adjuvant chemotherapy and/or irradiation is generally given, even following apparent gross total resection, owing to their invasiveness and guarded prognosis (median survival 6 mo in one series). For patients undergoing subtotal resection of CPCs, or with leptomeningeal dissemination at presentation, both carboplatin-based chemotherapy and focal or craniospinal irradiation are recommended as per the CPC-SIOP-2000 study. The benefit of chemotherapy was shown in a meta-analysis demonstrating superior survival with addition of chemotherapy, even in nonirradiated patients and patients with incomplete tumor resection (2-y OS 54% vs 24% without chemotherapy). A more recent single institution experience demonstrated 71% 5-year survival at 5 years in CPC patients treated with the chemotherapy and irradiation following maximal surgery, and the improved outcome with combined modality treatment was confirmed in another meta-analysis. PDGF receptor signaling has been suggested as a potential therapeutic target.

Colloid Cysts

Colloid cysts arise presumptively from the anlage of the paraphysis. These lesions grow in the anterior superior portion of the third ventricle as small, white cysts filled with homogeneous, gelatinous material. They do not usually cause symptoms until adulthood when there may be intermittent hydrocephalus causing unexplained headache. Although quite rare in children, colloid cysts should be considered in the differential diagnosis of persistent headache. Disturbance of the limbic system may cause emotional and behavioral changes in some instances. Colloid cyst of the third ventricle may be identified at autopsy in cases of unexplained death, including in adolescents and young adults. Colloid cysts are T2 hyperintense on MRI without enhancement. The treatment of choice is radical removal by open or stereotypically guided microsurgery. Other options are stereotactic cyst aspiration, ventriculoperitoneal shunting, transcortical/transcallosal resection, and endoscopic removal and marsupialization.

Ganglioglioma and Related Glioneuronal Tumors

Gangliogliomas are rare, glioneural tumors that account for 2.5% of pediatric brain tumors. The peak age incidence is 10 to 20 years. They arise mainly in the temporal lobe but also in other cerebral lobes or spinal cord. The usual prodrome is a long history of refractory epilepsy. Imaging reveals a solid to cystic lesion with calcification on CT and hypometabolic activity on PET. The majority harbor BRAF V600E mutation, novel variants, or BRAF fusions, occasionally with CDKN2A homozygous deletion.

Total surgical resection is recommended, and prognosis for long-term seizure control is excellent. Malignant transformation to glioblastoma may follow incomplete resection. Radiation therapy and chemotherapy are of uncertain benefit. Vemurafenib has been used in BRAF-mutant ganglioglioma, with addition of cobimetinib to overcome resistance.

Desmoplastic infantile ganglioglioma (DIG) is a rare cerebral glioneural tumor of early childhood. DIGs are large hemispheric tumors that are generally benign, but deep lesions may be aggressive. Treatment is resection. Related glioneural tumors include desmoplastic astrocytoma of infancy and pleomorphic xanthoastrocytoma (PXA), which usually occur in the temporal lobe in adolescents and young adults. PXA (grade II) and anaplastic PXA (grade III, with requirement for more than 5 mitoses per 10 HPF) typically present with seizures and headache. These tumors enhance on MRI, are GFAP and S100 positive, and variably express neuronal markers such as synaptophysin. They may contain BRAF fusions. Treatment is surgical resection. Response to targeted therapy has been reported in DIG with BRAF alteration.

Dysplastic Gangliocytoma

Dysplastic gangliocytoma of the cerebellum (Lhermitte-Duclos disease) is a rare, benign hamartomatous entity characterized by

loss of normal cerebellar cortical architecture and may be associated with macrocephaly and mental retardation. The tumor may present in children or young adults, with cerebellar signs such as dysmetria and ataxia. MRI appearance is a well-circumscribed lesion with characteristic laminar pattern of alternating high and low T2 signal. Pathologically there is diffuse enlargement of the internal granular layer and molecular layers of the cerebellum, with replacement of the internal granular layer by dysplastic ganglion cells and axonal hypermyelination of the molecular layer. The dysplastic ganglion cells are synaptophysin positive with loss of PTEN protein expression and AKT and S6 phosphorylation, indicative of AKT/mTOR pathway activation. The lesions are generally incompletely resectable, so patients with worsening symptoms may be considered for mTOR inhibitors. The disorder has been linked with Cowden disease (autosomal dominant familial hamartoma syndrome, with increased risk of breast, uterine, and thyroid cancer). Cowden disease is characterized by germ line abnormalities in the PTEN/AKT pathway, specifically in the PTEN tumor suppressor gene. Adult-onset Lhermitte-Duclos disease is a major diagnostic criterion for Cowden disease. Successful treatment with rapamycin has been reported in an infant with Lhermitte-Duclos disease.

Dysembryoplastic Neuroepithelial Tumor

DNT is a rare, low-grade (WHO grade I), mixed neuronal and glial tumor often associated with intractable seizures in children and young adults. DNTs comprise up to 17% of underlying diagnoses in epilepsy surgery series. Cortical dysplasia is found in 30% of cases. Enhancement on MRI is patchy and multifocal; perfusion-weighted MRI and MRS may aid in diagnosis. Unlike other epilepsy-associated glioneuronal tumors, where seizures arise within the lesion, seizures associated with DNT are considered to arise from the surrounding dysplastic brain; thus, extended resection is preferred over lesionectomy alone. Risk factors for recurrent seizures include age older than 10 years and epilepsy duration more than 2 years prior to diagnosis.

Schwannoma (Neurilemmoma)

These tumors arise in Schwann cells that surround and insulate nerves, particularly the eighth cranial nerve (vestibular schwannoma or acoustic neuroma), thereby affecting balance and hearing. Schwannomas may also develop on exiting spinal nerves, resulting in cord compression. Schwannomas are rare in children and especially if bilateral should prompt investigation for NF-2. Treatment options include surgery and stereotactic irradiation.

Hearing loss is a serious complication of NF-2, and there is a need for medical treatments. Based on vascular endothelial growth factor (VEGF) expression in vestibular schwannomas, VEGF blockade with bevacizumab was shown to improve hearing in some patients associated with volume reduction in growing schwannomas. A follow-up study (including adolescents) showed durable responses in one-third of patients, and a VEGF receptor (VEGFR) peptide-directed vaccine capable of inducing VEGFR-specific cytotoxic T lymphocytes is in clinical trials.

Astrocytoma

Low-Grade Astrocytoma

Low-grade astrocytomas (WHO grades I and II) include superficial lesions in the cerebral or cerebellar cortex and deeper infiltrative lesions of the optic pathways and midbrain. Cerebellar astrocytomas constitute about one-third of posterior fossa tumors. The peak incidence is early in the second decade. These tumors arise most often in the lateral cerebellar hemispheres rather than in the vermis. Symptoms of clumsiness and unsteadiness may be present for months and eventually are accompanied by intermittent morning headache and vomiting. Midline lesions have a shorter symptom interval. Truncal ataxia, dysmetria, and papilledema are usually present at diagnosis. Head tilt may be present, but other cranial nerve palsies or long-tract signs are infrequent and suggest brainstem invasion. Cerebellar astrocytomas may be primarily cystic or solid, and cystic lesions may have a nodule (Fig. 150.16).

The typical juvenile pilocytic astrocytoma (WHO grade I) contains areas of compact fibrillated cells with microcysts and eosinophilic structures called *Rosenthal fibers*. These lesions have greater than 90% survival with surgery alone. The tumor and associated cyst should be removed completely, and if residual tumor is identified postoperatively, re-resection should be considered because irradiation will not delay tumor progression. Diffuse astrocytomas (WHO grade II) may infiltrate the brainstem and be more difficult to resect entirely, with more guarded prognosis for survival.

Cerebral hemisphere low-grade gliomas have a peak incidence between ages 2 and 4 years and again in early adolescence. In toddlers, there may be symptoms of increased ICP, developmental delay, and growth retardation and specific signs such as weakness, sensory loss, or vision deficit. These slow-growing pediatric tumors are far less likely than adult gliomas to undergo malignant degeneration. They are infiltrating, however, and may cause seizures, either generalized or focal, the latter particularly suggestive of an occult brain tumor such as a ganglioglioma.

CT often reveals a relatively homogeneous, low-density, variably enhancing lesion with indistinct margins. MRI is more sensitive, showing decreased T1- and increased T2-weighted signal and providing better resolution of tumor and edema. Fibrillary astrocytomas (WHO grade II) are the most frequent histologic variant; protoplasmic and gemistocytic variants are less common. Gross total resection often affords long-term disease control but may not be curative. Five-year survival rates are 75% to 85%. Radiation therapy at doses of 50 to 55 Gy may be given

FIGURE 150.16 Magnetic resonance imaging showing lateral location of a partly cystic partly solid cerebellar astrocytoma.

FIGURE 150.17 Coronal (A) and sagittal (B) magnetic resonance imaging of a large hypothalamic glioma.

postoperatively following incomplete resection or at progression at least in older children but reoperation should also be considered. For younger children with residual or recurrent tumor, chemotherapy (eg, vincristine and carboplatin) has been used in an attempt to defer radiotherapy, and prospective trials evaluating this approach are in progress.

Diencephalic and optic pathway gliomas constitute up to 5% of childhood CNS tumors. Unilateral optic nerve tumors are generally diagnosed in the first decade of life, and optic chiasm tumors tend to present either in infancy or the second decade. An association with NF-1 is present in 50% to 70% of patients with isolated optic nerve tumors and 10% to 20% of patients with optic chasm tumors. Adolescents are more likely to complain of slowly progressive vision loss. Infants are more likely to be evaluated because of strabismus, nystagmus, or developmental delay. Patients with contiguous optic nerve involvement usually present with proptosis and optic pallor or atrophy. Intraorbital lesions usually cause decrease in central vision, whereas chiasmatic tumors produce bitemporal hemianopic field cuts. Nystagmus may be present in the more involved eye, and amblyopia is common. With routine MRI of NF-1 patients, lesions may be detected before onset of symptoms. There may be endocrine disturbances, such as growth deceleration, precocious puberty, and diencephalic emaciation.

Thalamic lesions may cause acute hemiparesis or hemisensory loss, signs of increased ICP, seizures, or involuntary movements. Infants tend to have macrocephaly, psychomotor delay, and vision deficits. Hypothalamic tumors have insidious onset and may be associated with altered mental status, endocrine dysfunction, and focal neurologic deficits.

On CT or MRI, diencephalic gliomas are hypo- or isodense lesions with variable contrast enhancement. Larger lesions may be cystic (Fig. 150.17). Visual pathway tumors may be confined to the optic chiasm (Fig. 150.18) or may show abnormal enhancement along the optic tracts and radiations. This streaking phenomenon is best appreciated on MRI, particularly with FLAIR sequence. Most diencephalic tumors are low-grade pilocytic astrocytomas.

An increasingly recognized variant in infants and young children is pilomyxoid astrocytoma, a locally aggressive tumor

FIGURE 150.18 Sagittal (A) and coronal (B) magnetic resonance imaging of an optic pathway tumor.

(WHO grade II in WHO 2007 but subsequently not graded in WHO 2016). Thalamic tumors are often fibrillary astrocytomas, which can also be locally aggressive. The natural history of these lesions is unpredictable. Spontaneous regression has been noted. An increased MIB-1 labeling index identifies the more aggressive pilocytic astrocytomas. Visual pathway tumors have a particular tendency to spread to contiguous structures. The role of surgery is unclear.

Low-grade astrocytomas of the optic pathway, thalamus, and hypothalamus are generally unresectable. In patients with diffusely infiltrating lesions, especially with NF-1, diagnosis may be confirmed with near certainty on neuroimaging alone, and surgery may be deemed of little benefit.

Radiation therapy is an effective treatment for progressive unresectable low-grade astrocytomas. In the Children's Oncology Group (COG) ACNS0221 trial, 85 patients age 3 to 21 years with unresectable progressive, recurrent, or residual low-grade astrocytoma (predominantly pilocytic astrocytoma) were treated with 54 Gy three-dimensional conformal or intensity-modulated radiation therapy with a 5-mm CT venography margin. No patient received proton therapy. Children younger than 10 years were required to have received at least one chemotherapy course, and patients with NF-1 were ineligible. Five-year progression-free survival (PFS) and OS were 71% and 93%, respectively. Inferior outcome was associated with tumor size over 5 cm and nonpilocytic histology. The study did not include neurocognitive assessment. Proton therapy potentially reduces the radiation dose to developing brain tissue. A study of 174 children (median age 10 y) treated at a single center for nonmetastatic low-grade astrocytoma (predominantly pilocytic astrocytoma) found 5-year rates of local control, PFS, and OS of 85%, 84%, and 92%; brainstem or spinal location and dose less than 54 GyRBE were associated with inferior local control. The major disadvantages of radiotherapy are adverse endocrine and neurocognitive effects, especially in younger children. There is a need for studies comparing long-term outcomes following photon and proton therapy.

The major disadvantages of radiotherapy are adverse endocrine and neurocognitive effects, especially in younger children. Chemotherapy (based on vincristine and carboplatin) has been beneficial as initial treatment in younger children who have progressive optic pathway and hypothalamic/schismatic gliomas, delaying the need for radiotherapy by a median of 4 years; most eventually relapse, however, except for NF-1 patients who tend to have indolent disease. The same chemotherapy regimen has been advocated as initial treatment for infants with tumor-associated diencephalic syndrome of emaciation. OS for optic pathway gliomas exceeds 85% at 10 years but is less than 50% for thalamic low-grade gliomas and considerably worse for high-grade (especially bithalamic) astrocytomas.

Several chemotherapy regimens are active in pediatric low-grade astrocytomas. Two regimens were compared in a COG study for recurrent/progressive or symptomatic chiasmatic/hypothalamic tumors: carboplatin + vincristine (CV) and thioguanine + procarbazine + lomustine (CCNU) + vincristine (TPCV). Five-year event-free and OS rates across all tumor locations were 45% and 86%, respectively, with slightly better event-free survival (EFS) with TPCV and inferior survival with tumor location in the thalamus. A regimen of weekly vinblastine shows comparable activity, even in patients previously treated with CV or TPCV, and temozolomide also has single agent activity with the advantage of oral administration. A regimen of cisplatin + etoposide is also widely used, although a multicenter, prospective, randomized trial that comparing CV with CV + etoposide failed to demonstrate a difference in PFS and OS between the two regimens.

The best example of successful targeted therapy is SEGA, a low-grade glioma typically arising in individuals with tuberous sclerosis. SEGAs bear mutations in *TSC1* and *TSC2* genes and have dysregulated activation of mTOR signaling. An mTOR inhibitor, everolimus, shows substantial activity in patients with unresectable SEGAs; in a multicenter, phase III, placebo-controlled trial, 35% in the everolimus group had at least a 50% reduction in the size of the SEGA versus no reduction in the placebo group. Everolimus has also been reported effective in progressive NF-1–associated low-grade gliomas.

Because of histologic evidence of vascular proliferation in recurrent low-grade astrocytomas, treatment with antiangiogenic agents such as bevacizumab and lenalidomide has been explored. Single-agent bevacizumab produced clinical and radiologic responses in recurrent low-grade glioma, including improved visual fields in suprasellar cases, and some patients responded to rechallenge.

In separate studies, treatment of children with optic pathway gliomas with bevacizumab produced marked recovery of vision in addition to response on MRI, and bevacizumab was effective at reducing the size of prominent cystic components of low-grade astrocytomas.

Based on frequent occurrence of BRAF mutations and alterations in pilocytic astrocytomas, BRAF inhibitors are being tested in children with tumor progression. A large survey suggests that tumor progression may be more likely in tumors with BRAF single nucleotide variation compared to tumors with BRAF rearrangement. Case reports have documented activity for BRAF inhibitors (vemurafenib, dabrafenib) singly or in combination with MEK inhibitors (selumetinib, trametinib) for children, adolescents, and young adults with BRAF V600–mutated or KIAA1549-BRAF fused low-grade astrocytomas. Selumetinib has produced sustained responses in recurrent or progressive pilocytic astrocytoma and NF-1–associated low-grade astrocytomas and may become an alternative to standard chemotherapy in newly diagnosed patients. Selumetinib is also effective in unresectable plexiform neurofibromas in children with NF-1, producing durable tumor shrinkage with improved quality of life. Single-agent trametinib is also moderately effective in progressive low-grade pediatric astrocytomas.

Potentially actionable mutations in FGFR1, PTPN11, and in NTRK2 fusion genes have been identified in noncerebellar pilocytic astrocytomas, whereas rearrangements in the MYB family of transcription factors are frequent in pediatric grade II diffuse and anglocentric astrocytomas. Experience with sorafenib, a multikinase inhibitor of BRAF, VEGFR, PDGFR, and c-kit, provides a cautionary note, however, because treatment with sorafenib produced unexpected acceleration of tumor growth, perhaps by paradoxical ERK activation.

High-Grade Astrocytoma

High-grade astrocytomas account for about 10% of brain tumors in children and include anaplastic astrocytoma, oligodendroglioma, and oligoastrocytoma (WHO grade III) and glioblastoma multiforme and gliosarcoma (WHO grade IV). The WHO classification emphasizes degree of cellularity, nuclear and cellular pleomorphism, mitosis, endothelial proliferation, and necrosis. The 2016 revision of the WHO classification integrates molecular information and introduces distinct entities such as diffuse midline glioma H3K27M mutant (grade IV).

High-grade astrocytomas in children are aggressive tumors with high morbidity and mortality. Pediatric high-grade astrocytomas tend to arise de novo rather than from malignant transformation of a low-grade astrocytoma as may occur in adults. The majority of pediatric high-grade astrocytomas occur in the cerebral cortex or brainstem, less often in the midbrain and infrequently in the spinal cord. Common symptoms of cerebral cortical high-grade astrocytomas include headache, vomiting, seizures, motor weakness, and behavioral abnormalities. Cerebellar lesions may present with ataxia. Symptom duration is generally less than 3 months. Head CT is highly sensitive for the detection of high-grade astrocytoma, demonstrating heterogeneous density and diffuse contrast enhancement. MRI is necessary to confirm the anatomic origin and extent of the tumor. MRI findings include indistinct borders, mass effect, T1 hypointensity, T2 hyperintensity, and edema on FLAIR sequences. Leptomeningeal spread and distant metastases are uncommon.

Histologic criteria are the same in children as in adult high-grade astrocytoma.

Anaplastic astrocytomas (WHO grade III) are composed of astrocytes with increased cellularity, pleomorphism, and numbers of mitoses. There may be focal necrosis, but it may not be so extensive as to form pseudopalisades. In contrast to low-grade pilocytic tumors, anaplastic astrocytomas have an unstable vasculature, with a predominance of immature vessels distinguished by negative immunostaining for α-smooth muscle actin, and exhibit VEGF and anti–flt-1/VEGFR-1 immunoreactivity. Glioblastoma multiforme (WHO grade IV) has prominent vascular proliferation and a pseudopalisading pattern of necrosis.

Genetic changes in pediatric high-grade astrocytomas differ from adult tumors. EGFR amplification is uncommon, p53 pathway mutations are more common, and there tend to be fewer DNA copy number alterations. The most common focal alteration is PDGFRA amplification, sometimes associated with BRAF-V600E mutation.

Glioblastoma is subclassified as IDH wild-type, IDH mutant, or diffuse midline glioma H3K27M mutant (with histone H3.3 [H3F3A], H3.1 [HIST1H3B], or rarely HIST2H3C mutation at K27). IDH1-mutated cases are uncommon in pediatrics but have more favorable outcome than IDH wild-type cases (5-y OS 60% vs 20%).

The H3.3 K27M cases occur throughout the midbrain and pons between age 5 and 10 years and had have particularly poor prognosis (median survival 11 mo). H3.1 cases occur mainly in the pons at median age 5 years, with slightly longer median survival of 15 months; a high proportion have mutations in ACVR1. Another subtype with H3.3 (H3F3A) mutation at G34 presents in older children and young adults arising exclusively in the cerebral cortex (commonly with TP53 and ATRX mutations).

About 40% of pediatric glioblastoma multiform tumors lack histone and IDH1 mutations. Prognosis is intermediate between IDH1 mutant and H3K27M mutant cases, approximately 30% 3-year survival. This is the group characterized by gene amplification of PDGFRA, EGFR, CCND/CDK, and MYC/MYCN. Patients whose tumors have TP53 gene mutation or p53 overexpression and/or O^6-methylguanine-methyltransferase (MGMT) overexpression have inferior outcome.

Infant tumors appear to lack HOXA9/HOXA10, a tumor-promoting gene, possibly accounting for the better outcome of high-grade astrocytomas below age 3 to 4 years. Genomic subtypes are receptor tyrosine kinase–driven high-grade tumors, RAS/MAPK-driven hemispheric low-grade tumors, and RAS/MAPK-driven optic pathway/hypothalamic low-grade tumors.

Astroblastoma, previously defined histologically as a WHO grade III glial neoplasm with astroblastic pseudorosettes occurring in older adolescents and young adults, has been reassessed as encompassing distinct genetically defined entities, most often MN1 gene fusions or rearrangements.

Common symptoms of cerebral cortical high-grade astrocytomas include headache, vomiting, seizures, motor weakness, and behavioral abnormalities. Cerebellar lesions may present with ataxia. Symptom duration is generally less than 3 months. Surgery is important for diagnosis and for removing or debunking tumor and alleviating increased ICP; moreover, major resection improves survival. In children on Children's Cancer Group (CCG)-945 (involved field irradiation with adjuvant CCNU-based chemotherapy), 5-year PFS was 19% overall, but 40% of children with GTR were surviving. However, these infiltrative tumors may disseminate in the CSF and will almost certainly recur without further therapy.

Postoperative involved-field irradiation (59-60 Gy) and adjuvant chemotherapy both increase survival. The CCG Study-943 demonstrated a superior 5-year progression free survival with adjuvant vincristine, prednisone, and lomustine compared to radiation alone (44% vs 19%). The CCG-945 study compared that chemotherapy to a multiagent combination with comparable 5-year PFS (26% and 33%). Subsequent pathology review showed that a proportion of cases in these studies were actually low-grade astrocytomas, although the statistical benefit of chemotherapy for glioblastoma was upheld. Meanwhile, the addition of temozolomide to radiation was shown to improve survival in adults with glioblastoma, and this strategy was adopted in the COG protocol ACNS0126. Three-year EFS and OS were only 11% and 22%, however, with particularly poor outcome in cases with overexpression of the DNA repair enzyme MGMT, implicating temozolomide resistance. This possibility was addressed by coadministration of O^6-benzylguanine, which inactivates and depletes MGMT, in a Pediatric Brain Tumor Consortium; there was no improvement in the response rate. A subsequent COG study, ACNS0423, lomustine was added to maintenance temozolomide, with improved outcome compared to ACNS0126. Three-year EFS and OS were 22% and 28%; the difference was most pronounced for incompletely resected glioblastoma and cases with MGMT overexpression.

Adjuvant bevacizumab is approved for recurrent/progressive glioblastoma in adults, and bevacizumab with irinotecan (PBTC-022) was minimally effective for recurrent high grade glioma or high-grade glioma (HGG) in children. However, bevacizumab given during radiotherapy in newly diagnosed pediatric high-grade astrocytoma was no better than temozolomide (COG ACNS0822); the histone deacetylase inhibitor vorinostat given during radiotherapy was also not superior to temozolomide in that trial. Similarly, in the HERBY trial, addition of bevacizumab to temozolomide during radiotherapy did not improve progression-free survival, although there was a survival benefit for patients with hypermutator tumors (mismatch repair deficiency and somatic POLE/POLD1 mutations) and those biologically resembling PXA-like, driven by BRAF V600E or NF-1 mutation.

In patients with recurrent BRAF V600E–mutated high-grade astrocytomas (which may represent malignant transformation from a low-grade tumor), complete responses to vemurafenib or dabrafenib have been reported. Other targeted therapies are being investigated, including receptor tyrosine kinase inhibitors and PARP inhibitors. Alternative pharmacologic strategies such as convection-enhanced drug delivery are currently in clinical trials.

Irradiation-avoiding strategies have been used in young children with high-grade glioma. In Head Start II and III, 5-year EFS and OS were 25% and 36%, respectively. Children younger than 36 months old had improved 5-year EFS and OS of 44% and 63%.

High-dose chemotherapy with autologous stem cell rescue afforded occasional long-term survival in recurrent patients with minimal residual tumor following surgical debulking. Immune checkpoint inhibition has been effective in children with balletic mismatch repair deficiency, who are susceptible to leukemia and gastrointestinal cancers as well as brain tumors. Immunomodulating agents, oncolytic virotherapy, dendritic cell vaccines, and chimeric antigen receptor T cells are all being investigated as potential therapies.

Brainstem Glioma

Brainstem gliomas are a heterogeneous group. Small intrinsic tectal gliomas are indolent and may be managed conservatively. But the typical diffuse, intrinsic pontine lesions carry the worst prognosis of any childhood brain tumor. Brainstem tumors constitute 10% to 20% of posterior fossa tumors, with a peak incidence at ages 5 to 8 years. Most arise in the pons, and there may be contiguous spread to the medulla or midbrain. Despite the clinical aggressiveness of these tumors, the histologic appearance at initial diagnosis is quite variable, but at autopsy, most show anaplastic features. This may reflect sampling error at initial biopsy or subsequent malignant transformation. These tumors infiltrate the brainstem and compress normal structures while extending superiorly and inferiorly to produce diffuse enlargement of the brainstem. DIPGs are nearly uniformly fatal within 18 to 24 months. Some tumors extend ventrally, laterally, or posteriorly, and the primarily exophytic tumors tend to be more accessible to surgical resection and carry a better prognosis as do focal midbrain lesions.

The course is insidious with slowly progressive cranial neuropathy, motor symptoms and disturbance of gait, swallowing, and speech. Vomiting and headache indicate the presence of hydrocephalus, which is generally a late finding. Children with dorsal exophytic lesions may have more unsteadiness and less evidence of cranial nerve dysfunction. CT shows a low-density lesion in the brainstem, with compression and obliteration of surrounding cisterns but little if any contrast enhancement. Uncommonly, brainstem tumors may be isodense or hyperdense with cystic areas. MRI is preferred because of the detail appreciated on sagittal images typically revealing more extensive disease than appreciated on CT. The magnetic resonance appearance is of decreased signal intensity on T1-weighted images (**Fig. 150.19A**) and increased T2-weighted signal. Ring enhancement with contrast administration is prognostically unfavorable. MRI may also demonstrate infiltration of the medulla (**Fig. 150.19B**) or thalamus.

Given the accuracy of magnetic resonance diagnosis, the morbidity of surgery, and the variable prognostic impact of biopsy, it has been accepted that surgery is not warranted for most patients with diffuse intrinsic pontine lesions, in whom major resection when attempted has not improved survival. Biopsy may be offered in the context of research protocols accruing tissue samples for molecular studies or to guide selection of targeted therapies. Patients with exophytic, cervicomedullary tumors are more likely to benefit from surgery as are patients with atypical clinical courses or magnetic resonance findings (eg, symptom duration exceeding 6 mo, absence of cranial nerve findings primarily exophytic or focal ring-enhancing lesions). Children younger than age 3 years may fare better. Standard treatment is field-radiation therapy except for completely resected focal lesions. Most children with brainstem gliomas benefit at least transiently from radiation therapy to a dose of 54 to 56 Gy. Although leptomeningeal dissemination may occur, the main risk is for local recurrence. Median survival is only 9 to 12 months with 3-year survival of 13%.

Chemotherapy (including temozolomide and topotecan) and immunotherapy (such as β-interferon) have been unsuccessful in this condition, although new agents continue to be studied. Because about 80% of DIPG have histone H3.1 or H3.3 mutations, the histone deacetylase inhibitor vorinostat or the prodrug capecitabine have been tried with and following radiation therapy. Veliparib, a PARP inhibitor, added to radiation and maintenance temozolomide did not improve survival. An Akt/era and dopamine D_2 receptor inhibitor ONC201 is in clinical trials for H3K27M-mutated tumors. "Personalized treatment" adds

FIGURE 150.19 **A:** Sagittal magnetic resonance imaging of a diffuse brainstem glioma. **B:** Axial image showing infiltration.

individualized targeted therapies to a backbone of radiation and a combination of nimotuzumab, vinorelbine, and valproate. High-throughput drug screening with candidate validation in patient-derived xenografts and transcriptional and metabolic testing may identify drug combinations which are cytotoxic but also exploit key metabolic dependencies.

Another approach is regional tumor treatment by convection-enhanced delivery of drugs and immunotoxins. Determination of responses is complicated by interobserver variability in tumor measurement; the most consistent results are derived from FLAIR images. It has been suggested that clinical trials should incorporate other objective endpoints, such as survival, rather than radiologic response alone. Children with brainstem tumors should also be monitored for signs of hydrocephalus because CSF diversion by shunting or third ventriculostomy can improve quality of life.

Brainstem tumors in children with NF-1 are a distinct entity, occurring more often in the medulla than in the pons and associated with less aggressive behavior. The majority of such patients will survive without adjuvant treatment.

Spinal Cord Astrocytoma

Spinal cord astrocytomas account for about 4% of childhood CNS neoplasms. Other primary spinal cord tumors in children include gangliogliomas and ependymomas. Spinal high-grade astrocytomas are uncommon. Astrocytomas may occur in any part of the cord but are seen most often in the cervical region, with the solid component extending an average of five spinal segments. Most have benign histologic appearance and grow slowly. Symptoms and signs may include pain (ie, localized or radicular), weakness or spasticity, gait disturbance, and bowel or bladder dysfunction. Gadolinium-enhanced MRI is preferred for demonstrating the location of the solid tumor, associated cysts, and edema. Treatment may be attempted gross-total or near-total resection or partial resection with decompression of cysts with postoperative radiotherapy.

The degree of neurologic recovery depends on the preoperative condition of the patient. A potential complication is spinal deformity, resulting from laminectomy, radiotherapy, or both. About one-third of patients require a spine stabilization procedure. For children with low-grade tumors, survival rates of 55% at 10 years have been reported after partial resection and radiotherapy. Chemotherapy has been substituted for radiotherapy in very young children. The prognosis for children with high-grade tumors is worse, although 5-year PFS of 46% was reported in a study using combined radiation therapy and chemotherapy.

Oligodendroglioma

Oligodendrogliomas are a type of glioma originating presumably from oligodendrocytes or a glial precursor cell. They are more common in adults but account for about 1% of primary CNS tumors in children. The majority of patients present with seizures and finding of a tumor in the frontal lobe. Other symptoms are headache, vision change, and motor weakness. Oligodendrogliomas grow slowly but infiltrate nearby brain tissue and are divided into low- and high-grade variants according to degree of hypercellularity and pleomorphism (WHO grades II and III). Tumor cells have a distinctive monotonous round cell ("fried egg") appearance. A consistent finding is deletion or codeletion of chromosomal arms 1p and/or 19q. This finding correlates with chemosensitivity and improved prognosis, at least in anaplastic oligodendrogliomas and mixed oligoastrocytomas. Active regimens include procarbazine + lomustine + vincristine and single agent temozolomide (either standard 5-d cycles or low-dose extended dosing).

Medulloblastoma and Embryonal Tumors

Medulloblastoma

Medulloblastoma and supratentorial embryonal tumors (formerly supratentorial primitive neuroectodermal tumors) are collectively the most common malignant CNS tumors of childhood. The presumed cell of origin of medulloblastoma is derived from fetal external granular cells of the cerebellum or rests in the posterior medullary velum. These tumors account for about 30% of infratentorial tumors in children but are uncommon in adults.

Medulloblastomas typically involve the cerebellar vermis, grow to fill the fourth ventricle, and may infiltrate the floor of the ventricle and adjacent structures. The tumor may arise more laterally, especially in older children and adolescents. *Nonmedulloblastoma embryonal tumors* generally arise in the cerebral cortex. These lesions appear to originate from the germinal matrix of the primitive neural tube. A distinct entity is *ETMR*, characterized by C19MC amplification. Most are diagnosed before age 10 years. *Pineoblastoma* is a related lesion not included in the embryonal classification but treated similarly to medulloblastoma.

Children with medulloblastoma typically present with ataxia, diplopia, and symptoms of increased ICP (morning headache, vomiting, lethargy). Median age is 5 years, and symptom duration is often less than 3 months, and occasionally emergent if there is spontaneous in tumoral hemorrhage. Older children with laterally situated medulloblastomas may present with ipsilateral dysmetria and cranial neuropathies without hydrocephalus. Children with nonmedulloblastoma embryonal tumors present with headache and vomiting due to increased ICP; infants may have lethargy, irritability, and an enlarging head circumference. Supratentorial tumors may present with hemiparesis, seizures, and visual field defects. Upgaze paresis may be noted in pineoblastoma or with compression of the tectum of the midbrain.

These tumors appear isodense or hyperdense on CT and usually enhance homogeneously. Hydrocephalus is seen in more than 80% of patients. Other CT features include small cysts, calcification, and hemorrhage. MRI may give better indication of tumor extent (**Fig. 150.20A**) and possible leptomeningeal dissemination (**Fig. 150.20B,C**). MRI is also preferred over CT to facilitate evaluation of disseminated spinal tumor, which is found in up to one-third of patients with medulloblastomas.

Aggressive surgical resection is recommended for medulloblastoma and supratentorial embryonal tumors. The goal is complete or near-complete resection. In medulloblastoma, this is limited mainly by tumor infiltration of the fourth ventricle, the brainstem, or one of the cerebellar peduncles. Morbidity may include the posterior fossa syndrome of aseptic meningitis or (less commonly) mutism, pharyngeal dysfunction, and ataxia, with possible long-term sequelae. Placement of an external ventricular drain may be required, but preoperative ventriculoperitoneal shunting is not usually recommended due to the risk of upward herniation and because hydrocephalus will be relieved by tumor removal in most patients. Up to 30% of patients may require permanent shunting.

Postoperative MRI should be obtained within 48 hours to confirm the extent of resection. Spine MRI should be obtained if

FIGURE 150.20 Sagittal magnetic resonance imaging of a medulloblastoma in the posterior fossa **(A)** with coronal image showing parenchymal nodules **(B)** and spine images showing seeding of the cord **(C)**.

not already done preoperatively. Lumbar puncture for CSF cytology is also required at a safe interval after surgery, usually after 10 days to avoid false-positive results. Patients with medulloblastoma are stratified clinically as *average risk* (ie, localized posterior fossa medulloblastoma with no more than 1.5 cm^2 postoperative residual tumor) and *high risk* (ie, more than 1.5 cm^2 residual or dissemination outside the posterior fossa, including positive CSF cytology). Up to 40% of children will present with dissemination of medulloblastoma. The staging system for tumor extent is as follows:

- M0: no dissemination
- M1: positive CSF cytology only
- M2: gross nodular seeding in cerebellar/cerebral subarachnoid space and/or lateral or third ventricle
- M3: gross nodular seeding in spinal subarachnoid space
- M4: extraneural metastasis

It is now apparent that medulloblastomas comprise at least four distinct subtypes based on aberrant activation of signaling pathways regulating cerebellar development or oncogene amplification: (1) *Wnt tumors* (named for drosophila wingless) with classic histology and very good prognosis. Also termed *classic medulloblastoma*, this subtype has the histologic appearance of a small, round, blue cell tumor with a diffuse pattern of poorly differentiated cells. Neuroblastic ("Homer-Wright") rosettes may be present but are not required for diagnosis. Immunohistochemical staining is typically positive for synaptophysin and occasionally for neurofilament protein or GFAP, although the latter usually represents reactive intratumoral astrocytes. (2) *SHH tumors* (named for sonic hedgehog), relatively more common in infants and adults, with desmoplastic/nodular histology and intermediate prognosis (good in infants). This subtype arises in cerebellar hemispheres and is characterized by nodular islands of differentiating neuroblasts. An "extensively nodular" variant is recognized in infants. (3) *"Group 3" tumors* with overrepresentation of large cell/anaplastic histology, MYC amplification, very frequent metastasis, and poor prognosis. Large cell/anaplastic medulloblastoma vaguely resembles large cell lymphoma, with large neoplastic cells having vesicular nuclei and prominent nucleoli. Most group 3 medulloblastomas fall between these histologic extremes, but one-quarter exhibit at least moderate anaplasia. The presence of more than 50% large cell/anaplastic histology is considered a high-risk criterion, even if the tumor is localized and completely resected, because of more aggressive behavior. (4) *"Group 4" tumors* with classic histology but tendency for metastasis, occasional MYCN amplification, and intermediate prognosis.

Immunohistochemical correlations are nuclear positivity for β-catenin in Wnt tumors, GAB1 positivity in SHH tumors, and filamin A and YAP1 positivity in both. Correlation with cytogenetic

findings shows isochromosome 17q to be typical of group 3 and 4 tumors, monosomy 6 associated with Wnt tumors, and 9q and 10q deletion in SHH tumors. Profiling six fluorescent in situ hybridization biomarkers (GLI2; MYC; and chromosomes 11, 14, 17p, and 17q) reliably identifies very low-risk and very high-risk patients within SHH, group 3, and group 4 medulloblastomas.

In infants, medulloblastoma must be distinguished from AT/RT, which has not only a small cell component resembling medulloblastoma but also cords of cells in a mucinous background that resemble chordoma, with a rhabdoid appearance of the cytoplasm of the larger cells.

Exome sequencing has revealed subtype-specific somatic mutations in known medulloblastoma-related genes (CTNNB1, PTCH1, MLL2, SMARCA4) and genes not previously considered medulloblastoma-related (DDX3X, CTDNEP1, KDM6A, TBR1). In particular, mutant DDX3X potentiates transactivation of a TCF promoter and enhances cell viability in combination with mutant β-catenin. Growth factor–independent 1 family proto-oncogenes GFI1 and GFI1B have been identified as oncogenic drivers for groups 3 and 4 tumors, an example of "enhancer hijacking" wherein coding sequences are juxtaposed proximal to active enhancer elements. Epigenetic alterations also contribute to medulloblastoma tumorigenesis, including highly prevalent regions of hypomethylation correlating with increased gene expression.

Relatively less is known about the cytogenetic and molecular features of supratentorial embryonal tumors, but gene expression analysis shows distinct patterns of gene activation that differ from those of medulloblastoma. Three molecular subgroups have been proposed based on differential expression of cell lineage markers LIN28 and OLIG2: (1) primitive neural (younger females with poorest survival), (2) oligoneural (older males with best survival), and (3) mesenchymal (older males with highest incidence of metastatic disease and intermediate survival). A high-level amplicon involving the C19MC identifies an aggressive subgroup of embryonal tumors with distinct gene expression profiles and poor survival.

Children with average-risk medulloblastoma have approximately 80% 5-year disease-free survival, whereas high-risk children have approximately 65% 5-year survival. Infants younger than age 3 years have inferior outcome and are considered high-risk patients even with localized tumors; an exception appears to be SHH tumors in infants for whom de-escalation of therapy may be considered.

Radiation therapy is the standard postoperative treatment for medulloblastoma and nonmedulloblastoma embryonal tumors. Craniospinal irradiation is given because the entire neuraxis is at risk for tumor recurrence. Conventional doses are 23.4 (average-risk patient) to 36 Gy (high-risk patient) to the brain and spine, with a boost to the local tumor site to a dose of 54 to 55.8 Gy. Radiotherapy should be initiated within 4 to 6 weeks. Proton therapy may be advantageous because during spine treatment there will be lesser dose scatter to the anterior chest and abdomen. Intellectual outcome is reported to be better after proton therapy compared to radiotherapy.

Historically, adjuvant (postirradiation) chemotherapy with vincristine and lomustine was introduced for high-risk medulloblastoma and shown to improve survival; the addition of cisplatin afforded a remarkable 5-year PFS rate of 85% in one series. Preirradiation chemotherapy did not improve survival. Accordingly, adjuvant chemotherapy was introduced for average-risk patients, and the combination of reduced dose neuraxis irradiation with weekly vincristine, followed by vincristine + lomustine + cisplatin chemotherapy (COG A9961), resulted in a 5-year PFS rate of 79%. Other successful regimens include alternating vincristine + lomustine + cisplatin and vincristine + cyclophosphamide or higher dose cyclophosphamide (with peripheral stem cell support) allowing reduction of vincristine and cisplatin. Treatment regimens for high-risk medulloblastoma generally incorporate dose-intensified vincristine + cisplatin + cyclophosphamide, affording 50% to 70% survival, including patients with metastatic disease. Side effects include high-frequency hearing loss and renal insufficiency with cisplatin and myelosuppression with lomustine and cyclophosphamide. Vincristine side effects include alopecia, constipation, and occasional syndrome of inappropriate antidiuretic secretion. Vincristine can cause dose-limiting peripheral neuropathy; substitution of vinblastine appears to be safe.

Radiation therapy is deferred in infants, in favor of dose-intensive chemotherapy. Addition of high-dose methotrexate to a cisplatin/cyclophosphamide-based infant protocol resulted in 49% 3-year EFS. Best results were in infants with nondisseminated totally resected tumors with desmoplasia histology. A series of trials using higher dose, marrow-ablative chemotherapeutic regimens supported by autologous peripheral blood stem cell rescue have shown that infants younger than 3 years at diagnosis of medulloblastoma can be treated successfully with deferred or no radiotherapy (3-y EFS 67% for M0 and 49% for M+0). Based on favorable results, the upper age for this approach has been extended to 6 years. Early tumor progression on chemotherapy has remained a major problem. Addition of high-dose methotrexate to cisplatin-based chemotherapy for young children with newly diagnosed disseminated medulloblastoma (including autotransplant consolidation) resulted in a high response rate and 49% 3-year EFS.

Some protocols for older infants combine local tumor irradiation (ie, using confocal techniques) and chemotherapy, either conventional or high dose (with autologous stem cell rescue). Another strategy has been to incorporate intraventricular methotrexate with systemic chemotherapy, as in the HIT 2000 trial, with the goal of avoiding irradiation. In that study, children younger than age 4 years with desmoplastic/nodular histology had 93% progression-free and craniospinal radiation-free survival at 5 years, without excessive neurotoxicity.

With recognition of the four subtypes of medulloblastoma, it may be possible through preclinical testing to identify chemotherapeutic agents with selective effectiveness against particular subtypes. For example, screening murine group 3 medulloblastomas against a library of 7,000 compounds in a high-throughput cell-based assay revealed synergistic antitumor activity of pemetrexed and gemcitabine as combination therapy in group 3 tumors overexpressing MYC.

For recurrent medulloblastoma, the combination of temozolomide + irinotecan appears active, as does temozolomide + topotecan or single-agent oral etoposide. Recurrence tends to be local in SHH medulloblastoma and metastatic in group 3 and 4 tumors. Overall prognosis following recurrence is guarded. Targeted therapy with agents such as SHH inhibitors is under investigation. High-dose chemotherapy with hematopoietic stem cell rescue has been used for selected patients with recurrent medulloblastoma who remain chemotherapy-sensitive. Increasing pursuit of targeted therapy may be anticipated following successful treatment of a young adult with SHH-driven medulloblastoma with the hedgehog pathway inhibitor GDC-0449 and demonstration of antitumor activity of

vismodegib in a child with SHH medulloblastoma. Newer approaches include radioimmunotherapy with monoclonal antibody conjugates (as used in neuroblastoma), and preclinical studies of direct infusion of drugs into the fourth ventricle or infusion of autologous ex vivo expanded natural killer cells or chimeric antigen receptor T cells into CSF.

Nonmedulloblastoma Embryonal Tumors

For nonmedulloblastoma embryonal tumors, the same treatment approach of maximal resection, craniospinal irradiation, and adjuvant chemotherapy has been pursued. Prognosis is worse compared to medulloblastoma, generally less than 40% 5-year survival even for localized tumors. Moreover, there is no histologic or molecular system of tumor subclassifications to guide therapy. Hyperfractionated radiotherapy with cisplatin-based maintenance chemotherapy (HIT 2000) afforded 58% 5-year survival. Preirradiation chemotherapy was not helpful for older patients. Radiation may be deferred in the youngest patients, in whom dose-intensive chemotherapy can offer similar outcomes; radiotherapy can then be tailored to chemotherapy response.

ETMR includes three histologic variants with identical molecular findings (LIN28A positive, C19MC mRNA amplification, and trisomy 2) all arising in infants and young children in supratentorial cortical or paraventricular sites. *Ependymoblastoma* was previously considered to be a variant of ependymoma, whereas *embryonal tumor with abundant neuropil and true rosettes* was originally described as a primitive neuroectodermal tumor. The third variant, *medulloepithelioma*, is also an aggressive cerebral hemispheric tumor of infants and young children but shows a range of differentiation from embryonal primitive neuroepithelioma to variants exhibiting maturation. A review of the French experience with this group of tumors managed with multimodality therapy showed 1-year EFS and OS of 36% and 45%, respectively. Better survival was associated with radical resection, tandem high-dose chemotherapy, and risk-adapted radiation. Localized medulloepithelioma in the eye or orbit may be curable by radical surgical resection.

Central neurocytoma is a WHO grade II neuroepithelial intraventricular tumor typically presenting in older children or young adults with hydrocephalus and occasionally seizures. Variants include cerebral (extraventricular) neurocytoma and ganglioneurocytoma (with ganglion cell differentiation). Histologic appearance may resemble oligodendroglioma. Surgical resection is curative, with radiotherapy, stereotactic radiosurgery, and/or chemotherapy for incompletely resected or recurrent tumors.

Recurrent CNS embryonal tumors have guarded prognosis, generally less than 25% survival. Biopsy or surgical resection may be necessary to distinguish recurrent embryonal tumor from radiation necrosis or a new primary tumor such as meningioma or high-grade astrocytoma. Molecular studies may reveal emergent targetable mutations at the subclonal level. Children managed initially with deferral of radiation may benefit from local or craniospinal irradiation at tumor progression; this should be particularly considered in patients with recurrent medulloblastoma who can undergo complete resection of tumor. Other patients may be offered reirradiation at primary or metastatic sites, including the option of stereotactic irradiation. Recurrent CNS embryonal tumors may respond at least transiently to chemotherapy, with single-agent etoposide, topotecan, or temozolomide; combined temozolomide/irinotecan; and multiagent metronomic protocols containing bevacizumab. High-dose chemotherapy with autologous peripheral blood stem cell rescue has been used with variable results; interpretation of results is confounded by whether transplant outcomes are reported on an intent to treat basis. New agents may be efficacious in particular disease subtypes, such as vismodegib in recurrent sonic hedgehog medulloblastoma.

Pineoblastoma and Trilateral Retinoblastoma

Pineoblastomas are excluded from the revised embryonal tumor group classification and fall into distinct molecular subgroups with homozygous loss of function alteration in microRNA biogenesis genes (DICER1, DROSHA, DGCR8) or recurrent alteration in MYC–miR-17/92-RB1 pathway genes. Pineoblastoma has generally been treated similarly to medulloblastoma with similar 70% 5-year EFS following craniospinal irradiation and multiagent chemotherapy. Prognosis has been consistently worse in infants, including in the Head Start series of protocols, with early disease progression during induction chemotherapy. Pineoblastomas must be distinguished from pineal germ cell tumors (discussed separately) and pineocytomas (benign pineal parenchymal tumors treated by surgery alone or with radiotherapy).

Rb is an uncommon eye tumor of very young children, accounting for 3% of childhood cancers. Rb arises in the retina and may extend to the vitreous (with leukocoria), macula (with strabismus), optic nerve, and choroid, with risk of CNS and systemic dissemination. In 25% to 30% of cases, Rb is heritable (due to germ line RB1 mutation), including 15% of children with unilateral disease and all cases of bilateral disease. Rarely, children with bilateral Rb develop an intracranial neuroblastic tumor, resulting in "trilateral" Rb. The intracranial lesion most often occurs as pinealoblastoma and may initially be interpreted as a benign pineal cyst. Because most deaths from Rb have been due to trilateral Rb, MRI screening of infants with heritable Rb for pineal involvement has been advocated up to age 3 years.

Atypical Teratoid/Rhabdoid Tumor

CNS AT/RT is a rare, highly aggressive embryonal tumor of infants and young children accounting for up to 20% of infant cases in some series. About half present at supratentorial sites and half in the posterior fossa. Symptom duration is typically quite brief, with disease dissemination in about 20%. ATRTs have monosomy or deletion of chromosome 22. Fundamental to pathogenesis are somatic and germ line inactivating mutations of SMARCB1 (previously INI1/hSNF5) and SMARCA4 tumor suppressor genes, which are also mutated in renal rhabdoid tumors. The 2016 WHO classification defines AT/RT by the presence of either *SMARCB1* or *SMARCA4* alterations. Tumors with histologic features of AT/RT that lack these genomic alterations are termed *CNS embryonal tumor with rhabdoid features*. Three biologically distinct subsets of AT/RT have been described: AT/RT TYR (a melanosomal gene encoding tyrosinase, seen in infants), AT/RT SHH (with increased expression of sonic hedgehog pathway genes, seen in toddlers), and AT/RT MYC (with elevated MYC expression, in slightly older children). Reported median survivals are 37 months, 16 months, and 13 months, respectively.

Outcome for AT/RT with conventional chemotherapy has been poor (median survival <12 mo), but 2-year PFS of 53% was achieved with surgery, radiation therapy, and parenteral and intrathecal chemotherapy based on the Intergroup Rhabdomyosarcoma Study III. Better outcome has been associated with older age, localized presentation, and gross total resection. Radiation therapy

and intensive chemotherapy both contribute to survival. Protocols combining surgery, intensive chemotherapy with autologous peripheral blood stem cell rescue, and response-based irradiation have improved outcome for older children with AT/RT and are being evaluated in infants. In the COG ACNS0333 trial, 4-year EFS was 37% and OS 43%, uninfluenced by timing of radiation (pre- or posthigh-dose chemotherapy consolidation). Nearly all relapses occurred within 2 years and were predominantly local. Development of new agents is focussed on EZH2 inhibitors, targeting an obligatory dependence of cells with *SMARCB1 or SMARCA4* loss.

Ependymoma and Other Tumors

Ependymoma

Ependymomas constitute 5% to 10% of all primary childhood brain tumors and also occur in adults. Most ependymomas appear to be histologically mature (WHO grade II). Subtypes include papillary clear cell and tanycytic ependymoma (all WHO grade II). Variants include anaplastic ependymoma (WHO grade III, with increased cellularity and mitotic activity, microvascular proliferation and necrosis), which carries a worse outcome in some series, and the clinically indolent subependymoma and myxopapillary ependymoma (WHO grade I). "Ependymoblastoma" is no longer retained and is reclassified as an ETMR.

The 2016 WHO classification of supratentorial ependymomas includes RELA-positive and RELA-negative/YAP1-positive tumors. ST-EPN-RELA ependymoma presents at a median age of 8 years and has poor prognosis (5-y PFS 29%), although outcome is better in the clear cell ependymoma subset. ST-EPN-YAP1 tumors are less common, occurring mainly in infants. These tumors exhibit gene fusions involving YAP1, usually with MAMLD1. Prognosis is better that for ST-EPN-RELA (5-y PFS 66%). Both ST-EPN-RELA and ST-EPN-YAP1 may have anaplastic or nonanaplastic histology.

Transcriptional profiling of infratentorial ependymomas reveals two demographically, genetically, and clinically distinct groups: (1) younger patients (median age 2.5 y) with laterally located tumors with tendency for metastatic recurrence and poor PFS (18% at 5 y) versus (2) older patients (median age 20 y) with much better EFS (91% at 5 y). Both PF-EPN-A and PF-EPN-B may have anaplastic or non anaplastic histology.

Ependymoma and subependymoma may occur as primary spinal cord tumors, usually in adults. Myxopapillary ependymoma may be seen in children, typically arising in the distal spinal cord, with a tendency to disseminate early to the upper cord or brain.

Clinical symptoms depend on tumor location. About two-thirds of ependymomas occur in the posterior fossa. Tumors filling or compressing the fourth ventricle produce obstructive hydrocephalus with nausea, vomiting, and morning headaches. Tumors arising low in the fourth ventricle and extending into the lower medulla may cause neck pain, whereas cranial nerve palsies may result from brainstem invasion or compression of cranial nerves. In patients with supratentorial lesions, seizures and focal deficits are seen. Features on CT include calcification and variable enhancement. MRI will better demonstrate invasion by posterior fossa lesions into the brainstem (Fig. 150.21) or upper cervical spinal cord. Diagnostic evaluation includes spine MRI and lumbar puncture for CSF cytology.

FIGURE 150.21 Magnetic resonance appearance of an ependymoma showing tumor extension through the foramen of Luschka *(arrow)* and invasion of the brainstem.

Treatment of newly diagnosed intracranial ependymoma includes maximal surgical resection, involved field irradiation (conformal, intensity-modulated radiation therapy, or proton, 54-59.4 Gy), and chemotherapy. Postoperative residual disease may be managed by chemotherapy and second-look surgery prior to radiation therapy. Disseminated disease is typically managed with craniospinal irradiation with or without chemotherapy. Completely resected localized supratentorial nonanapestic ependymoma has been managed recently without radiation therapy, with progression-free survival in about two-thirds of cases. Infants with ependymoma may be given chemotherapy postoperatively with the goal of deferring radiation therapy, although involved field irradiation does improve survival outcome and is generally offered by age 12 to 18 months.

The most important predictor of outcome is the extent of surgical resection as confirmed by postoperative imaging. Successive clinical trials for ependymoma show that the rate of complete resection has increased from 50% to 75%. Resectability of posterior fossa lesions may be limited by brainstem infiltration, extension into the cerebellar pontine angle, or involvement of cranial nerve nuclei. Supratentorial lesions may also be infiltrative and difficult to remove. Gross total resection of ependymomas followed by involved-field irradiation to 55 Gy (tumor bed with 1-cm margin) affords up to 75% survival, whereas local recurrence is more likely following subtotal resection, and survival rates drop below 30%.

Patients with tumor dissemination at diagnosis (fewer than 10% of cases) do poorly. Additional poor prognosis factors include younger age at diagnosis, anaplastic histology, and tumor expression of the enzymatic subunit of telomerase (hTERT) and expression of the neural stem cell marker Nestin.

Adjuvant chemotherapy may improve outcome based on the responses of recurrent ependymomas to cisplatin and other agents and responses in infants. Preirradiation cisplatin-based chemotherapy for patients with postoperative residual tumor (CCG-9942) produced objective responses in 57% of patients, and 5-year EFS of patients receiving chemotherapy for incompletely resected tumors equaled that of patients with complete resection and no chemotherapy (55% vs 58%). The

COG ACNS0121 trial introduced observation for classic supratentorial ependymoma after gross total resection, and for the remaining patients gave conformal radiation after gross total or near-total resection, and for subtotal resection preirradiation chemotherapy with second-look surgery. The 5-year EFS rates were 61%, 37%, and 68% for observation, subtotal resection and GTR/near-total resection groups, respectively. A successor study (ACNS-0831) randomizes patients to postradiation chemotherapy versus radiation alone.

Primary postoperative chemotherapy with irradiation at progression has been reported in children younger than age 5 years with 59% 4-year survival (23% without irradiation). A similar study in children younger than age 3 years found 61% survival at 3 years leading to a larger study (POG-9233/34) demonstrating that with prolonged dose-intensive chemotherapy, 40% of infants with ependymoma could survive without radiotherapy. Infants younger than 3 years on the SJYC07 protocol received postoperative chemotherapy and consolidate focal conformal radiation, with 4-year PFS 75% and OS 92%. Based on Head Start protocol experience, there is no benefit of myeloablative chemotherapy with autologous stem cell rescue, although one report suggests a survival advantage in the group with anaplastic ependymoma.

Treatment of myxopapillary ependymoma is surgery, with increasing use of adjuvant irradiation.

Recurrent ependymomas are managed by resection, possible reirradiation of stereotactic radiosurgery, and chemotherapy. Active agents include cisplatin and carboplatin, etoposide, temozolomide, vincristine, and cyclophosphamide.

Prospects for targeted therapy focus on histone deacetylase inhibitors, γ-secretase inhibitors (blocking notch signaling pathway activation), telomerase inhibitors (in hTERT-positive ependymoma), and lapatinib (a dual EGFR antagonist). Potential predictive biomarkers were analyzed prospectively in an Italian cooperative group trial; better outcome was associated with lower hTERT mRNA expression and nucleoli protein expression; mRNA expression levels of EGFR and prominin 1/CD133 were not significant on multivariate analysis, although the prominin 1/CD133 cancer stem cell marker was strongly expressed in a substantial fraction of cases and appeared to be associated with more indolent disease.

Central Nervous System Germ Cell Tumors

CNS germ cell tumors tend to arise in the pineal and suprasellar regions (infundibulum and pituitary stalk). Germ cell tumors account for 3% to 4% of brain tumors in Western countries, but up to 15% in Japan and other parts of Asia. They account for about half of all pineal tumors and 5% to 10% of parasellar lesions. Pineal germ cell tumors account for half of all pineal tumors and have a male preponderance, presenting in adolescence. Suprasellar germ cell tumors predominate in younger females. Rarely, patients may present with synchronous suprasellar and pineal tumors.

CNS germ cell tumors are classified as germinoma, embryonal carcinoma, yolk sac tumor, choriocarcinoma, teratoma (mature or immature), teratoma with malignant transformation, and mixed germ cell tumor. About 50% to 65% of germ cell tumors are germinomas, histologically primitive lesions resembling gonadal germ cell tumors and presumably derived from embryonic migration of totipotent germ cells. Among nongerminomatous germ cell tumors, teratomas and mixed germ cell tumors are variously composed of mature, immature, and malignant elements. Choriocarcinomas are rare but highly malignant.

Chromosomal comparative genomic hybridization analysis of CNS germ cell tumors suggests that genomic alterations are essentially indistinguishable from those found in extracranial germ cell tumors. Mutations in the KIT/RAS signaling pathway are found frequently, or in the AKT/mTOR pathway, with global hypomethylation and chromosomal instability.

Symptoms and signs of pineal region germ cell tumors most often include headaches and Parinaud syndrome of upgaze paresis, convergence nystagmus, and light-near pupillary response dissociation. With extension to the overlying thalamus, there may be hemiparesis, incoordination, vision disturbances, or movement disorders. Suprasellar germ cell tumors produce pituitary and hypothalamic dysfunctions (notably diabetes insipidus) but usually not vision loss. CT appearance is of an irregular lesion of mixed density, occasionally with calcification and with variable enhancement.

MRI is more sensitive for purposes of follow-up evaluation. MRI may reveal a pineal cyst in otherwise healthy children being evaluated for headache; lack of hydrocephalus and Parinaud syndrome should lead one away from the diagnosis of a pineal tumor. Diagnosis may be aided by measurement of AFP and β-subunit of HCG, which are secreted by germ cell tumors but not pineal parenchymal cell tumors or cysts and are detectable in serum and CSF. Pure germinomas and mature teratomas are negative for AFP and HCG; germinomas with syncytiotrophoblastic elements may have low levels of HCG. AFP is elevated in endodermal sinus tumors and some immature teratomas; HCG is elevated in choriocarcinoma and embryonal carcinomas. Elevations of both indicate the presence of mixed malignant elements. Even with tumor marker elevation, however, histologic confirmation is recommended.

Surgery for pineal region germ cell tumors is technically difficult, but major resections may be achieved with acceptable morbidity rates by the use of supratentorial suboccipital or infratentorial supracerebellar approaches. Most patients require CSF shunting. There may be transient visual migraines caused by occipital lobe contusions. Teratomas may be encapsulated and are therefore easier to remove. Germ cell tumors may disseminate throughout the neuraxis in up to 10% of cases. Extracranial spread to lung and bone has also been reported.

Radiotherapy is the standard treatment for pure germinomas, given in the past as 35 to 45 Gy to the brain and spine with a 10- to 15-Gy boost to the area of the tumor, affording 90% survival at 5 years. More recently, craniospinal doses were reduced to 24 to 36 Gy (with tumor boost to 40-50 Gy) with comparable survival outcome. Addition of neoadjuvant carboplatin/etoposide chemotherapy may allow further reductions in the dose and extent of irradiation, potentially lessening the considerable endocrine, neuro-ophthalmologic, and neuropsychological sequelae of treatment.

Survival rates for mixed malignant germ cell tumors have been considerably lower, especially with radiotherapy alone, but have improved with the addition of chemotherapy. Current protocols are based on cisplatin- or carboplatin-containing regimens active in gonadal germ cell tumors; following chemotherapy, patients receive response-based radiation to protocol-defined fields (craniospinal or whole ventricular). For incomplete responders, second look surgery is an option. With craniospinal irradiation, 5-year EFS exceeds 80%, and a current protocol is investigating whether this result can be maintained

with radiation limited to the whole ventricular system. High-dose chemotherapy with autologous stem cell rescue is an effective strategy in recurrent germ cell tumors and has also been added for tumors refractory to initial therapy. Patients with germinoma recurrence following chemotherapy alone should be referred for radiation therapy, and reirradiation may also been offered.

Central Nervous System Lymphoma

Primary CNS lymphomas are rare both in children and adults, constituting fewer than 1% of intracranial tumors. They may occur at any age and are generally of B-lymphocyte origin, including Burkitt type, and can be a manifestation of congenital or acquired immunodeficiency, particularly HIV-associated. The tumor location is usually the cerebral cortex. CNS lymphomas appear isodense or hyperdense on CT with enhancement. MRI shows an iso- to hypointense lesion on T1-weighted images and iso-, hypo-, or slightly hyperintense lesion on T2-weighted images with variable enhancement. Whole-body ^{18}F-fluorodeoxyglucose PET may reveal extracranial sites of disease not seen on other imaging such as CT scan. An unusual presentation was progressive panhypopituitarism in a 15-year-old immunocompetent adolescent male on growth hormone for 3 years for growth deceleration; baseline MRI had been normal, but repeat MRI revealed a lesion in the pituitary stalk, which was a high grade B-cell lymphoma. Whole-brain irradiation has produced survival rates of only 20% to 30% in adults. A prospective trial in immunocompetent adults with primary CNS lymphoma showed that preirradiation high-dose methotrexate chemotherapy improved survival rates over whole-brain irradiation alone but with additive life-threatening neurologic toxicity. For these reasons, methotrexate- and cytarabine-based chemotherapy without irradiation is now the preferred treatment in both adults and children. The addition of rituximab was advantageous in an adult study in non-HIV patients. Intrathecal chemotherapy may be added in the event of positive CSF cytology. Consolidative high-dose thiotepa-based chemotherapy with autologous peripheral blood stem cell rescue has been used in responding younger patients. Newer agents used at recurrence in adults include ibrutinib and lenalidomide. Salvage irradiation is also an option. There is a case report of response to rituximab (intravenous and intraventricular) in a child with refractory primary CNS lymphoma.

Meningioma and Mesenchymal Tumors

Meningiomas are rare in childhood, accounting for 2.5% of pediatric brain tumors. Meningiomas can be associated with NF-2, and this diagnosis should be sought in any child with meningioma. Meningiomas may also occur in previously irradiated sites. These tumors usually arise on the meningeal surface but (in contrast to adults) may grow as parenchymal lesions presumably from meningeal cell rests. CT and MRI show an isointense or hyperintense lesion enhancing with contrast (Fig. 150.22).

Most lesions are clinically benign (grade I), although 10% of pediatric or NF-2–associated tumors show anaplasia (grade III) and 50% have atypical features (grade II). Overall prognosis is worse than in adults. High mitotic index, MIB-1 labeling index, and variant histology (eg, papillary, clear cell) are associated with invasiveness and adverse outcome. Deletions of NF-2, DAL-1, and chromosome 1p and 14q are common. Surgery is the primary treatment. Radiotherapy is of uncertain value but has been used for recurrent tumors, especially after unsuccessful

FIGURE 150.22 Axial magnetic resonance imaging of a meningioma.

reresection. Meningiomas may occasionally involve the leptomeninges, primarily, and these tumors (ie, meningeal sarcomas) tend to behave aggressively. Treatment has been combined radiation and chemotherapy.

Meningeal sarcomas may extend intracranially from the skull or arise directly from the dura or develop within meningiomas. Treatment includes surgery, radiotherapy, and chemotherapy guided by the particular histologic subtype. *Fibrous histiocytomas* arise from the dura or grow in brain parenchyma. Benign variants are curable by surgical resection, but malignant fibrous histiocytoma has guarded prognosis despite multimodality therapy. Solitary fibrous tumors arise from the dura and grow slowly; they are distinguished from fibrous meningioma by immunohistochemical positivity for CD34, vimentin, and BCL2. Surgical resection is curative.

Hemangiopericytomas occur mainly in adults, grow rapidly, and may present with seizures. Local recurrence is a problem as well as neuraxis spread and extracranial metastasis; radiotherapy and chemotherapy (including antiangiogenic agents) may be useful.

Malignant Melanoma

Primary malignant melanomas arise in children as well as adults, usually associated with the meninges (whereas metastatic lesions more commonly involve the brain parenchyma), with gadolinium enhancement on MRI and possible leptomeningeal spread. Most lesions contain melanosomes, and electron microscopy can confirm the diagnosis. Prognosis is poor, and tumors are radioresistant, although newer targeted therapies may supplement surgery. *Meningeal melanocytomas* occur mainly in adults and arise in the posterior fossa or spinal cord. Without complete resection, these lesions may transform to malignant melanoma.

LATE EFFECTS OF TREATMENT AND QUALITY OF LIFE

The health of children surviving brain tumors is generally worse than that of survivors of other childhood cancers. Children with supratentorial astrocytomas or craniopharyngioma have a

lower health status index than children with other types of brain tumors. A survey of health-related quality of life in childhood brain tumor survivors found cognitive impairment in two-thirds of the children and pain in almost one-third. Global health status was lowest in children given radiation therapy before age 5 years and in those with residual disease. Even among survivors of pediatric low-grade glioma who continue to have excellent long-term survival into adulthood, the greatest risk factor for death in multivariate analysis was administration of radiation.

Another survey of residual physical handicap in survivors found motor impairment in 56% of patients, cognitive impairment (ie, IQ score <80) in 30%, visual impairment in 24%, and epilepsy in 21%.

A study of psychological outcomes in long-term survivors found that the prevalence of psychological distress (11%) exceeded that in siblings (5%) and was not a direct result of cancer treatment but rather was associated with diminished social functioning and vocational skills. Another report found increased risk of hospital admission was the focus for psychiatric disorders among patients with brain tumors who had survived at least 3 years from diagnosis compared to other childhood cancer survivors, in whom there was no increased risk.

Radiation Effects

Radiation effects include a transient somnolence syndrome of sleepiness, irritability, anorexia, and headaches lasting about a week. Radiation necrosis develops in 0.1% to 5.0% of patients after conventional treatment at 50 to 60 Gy in daily fractions of 180 to 200 cGy. The onset may be within 3 months and is usually seen by 3 years, although occasionally not until much later; the symptoms and signs are those of a recurrent intracranial mass with possible seizures and progressive neuropsychological impairment. Surgical resection may be considered, but the disease may be multifocal following craniospinal irradiation. Medical management includes corticosteroids and usually a trial of bevacizumab.

Cavernous hemangiomas (cavernomas) developed in 3.4% of children at a median of 37 months following radiotherapy for brain tumors. Median age at treatment was 7 years. These rare benign complications of radiation therapy occurs between 2 and 30 years after cranial irradiation. The relative risk of stroke for 5-year survivors of brain tumors was 29.0 compared to sibling controls with dose-dependent increased risk following cranial irradiation exceeding 30 Gy. Treatment is symptomatic.

Endocrine Dysfunction

Endocrine dysfunction may follow irradiation to the hypothalamus and pituitary. Doses as low as 18 Gy may produce growth hormone deficiency, and doses above 36 Gy may cause hypothyroidism and gonadal dysfunction in more than half of patients. Nearly 40% of brain cancer survivors in the Childhood Cancer Survivor Study were below the 10th percentile for height. Risk factors included age younger than 5 years at diagnosis and radiation therapy to the hypothalamic-pituitary axis. Growth hormone deficiency in the absence of other anterior pituitary hormone deficiencies in children receiving cranial irradiation for posterior fossa tumors suggests growth hormone is the hormone most sensitive to radiation injury.

The next most common pituitary hormone abnormality is gonadotropin deficiency. There is an increased risk for delayed puberty and infertility as well as precocious puberty, which can be managed with gonadotropin-releasing hormone antagonists. Frank adrenal insufficiency is uncommon. Hypothalamic obesity, a syndrome of intractable weight gain, is an uncommon but serious complication of hypothalamic irradiation at doses exceeding 50 Gy.

Hypothyroidism is relatively common, particularly in children receiving craniospinal irradiation, because the thyroid gland is in the treatment field. Central hypothyroidism is rare. Hypothyroidism contributes to poor growth and impaired school performance, so thyroid supplementation should be provided. There is also an up to 15-fold increased risk of subsequent primary carcinoma of the thyroid, particularly in females, and most commonly papillary carcinoma.

Children should be followed for measurement of linear growth, periodic thyroid function studies, and additional endocrine evaluation if there is precocious or delayed-onset puberty. Growth hormone treatment improves final height in children with growth hormone deficiency after brain tumor therapy. Growth hormone response depends on adequate thyroid function, and thyroid supplementation may be required. In the subset of patients in whom growth was further limited by early puberty, the combination of gonadotrophin-releasing hormone analogs and growth hormone is reported to improve prospects for attainment of target height. A survey of growth hormone replacement therapy in patients with medulloblastoma suggests a trend toward underutilization, despite ample evidence that there is no increased risk of brain tumor recurrence associated with growth hormone therapy. There is evidence of an increase in the already existing risk for second malignant neoplasms in patients previously treated with radiation therapy. This increased risk of second neoplasms in growth hormone–treated childhood cancer survivors is now listed in the United States labeling for recombinant human growth hormone products.

Cardiovascular and Pulmonary Effects

Cardiovascular late effects in children treated for brain tumors include increased risk of stroke, blood clots, and angina-like symptoms. Late effects are common in those treated with surgery and radiation and higher still in those treated with surgery, radiation, and chemotherapy.

Large-vessel arteriopathy was identified by magnetic resonance angiography in 8.7% of brain tumor survivors following cranial radiation (given at a median age of 6.3 y). These arteriopathies were considered radiation-induced based on localization to the radiation field and absence of other etiologies. One patient had a middle cerebral artery ischemic stroke 2.4 years postradiation, and another had symptoms concerning for transient ischemic attack. The remainder were asymptomatic, and arteriopathy was detected by screening magnetic resonance angiography; these individuals may be candidates for primary stroke prevention strategies.

Cardiovascular problems may be compounded by restrictive lung disease and cardiotoxicity in recipients of craniospinal irradiation or intensive chemotherapy. Among survivors of childhood brain cancer whose mean age was 26 years and mean posttreatment interval was 16 years, systolic blood pressures and waist-to-hip ratios were higher than controls, as were blood lipid abnormalities. These findings identify dyslipidemia, central obesity, and hypertension as controllable risk factors for cardiovascular disease.

Compared to siblings, survivors are at increased risk for chronic cough, need for supplemental oxygen, and pulmonary fibrosis. Survivors treated with craniospinal irradiation were 10 times more likely to report chest wall deformity. These patients should be monitored for scoliosis, which can interfere with lung function.

Neurologic Sequelae

Neurologic and neurosensory sequelae in adult survivors of childhood brain tumors include hearing loss, blindness, cataracts, and diplopia. Nearly half of the survivors have coordination problems, and one-quarter have motor control problems after radiation doses of 50 Gy to frontal brain regions. Seizures are reported in one-quarter of patients, especially after radiation doses of 30 Gy or more. Atonic seizures in particular are difficult to control and are associated with pervasive cognitive impairments. Patients treated with surgery alone generally have no more than minor neurologic impairment that does not interfere with activities of daily living.

Radiation therapy is a principal cause of neurocognitive disorders in children with CNS tumors. Other factors include acute or chronic increased ICP, tumor mass effect, poorly controlled seizure disorders, hormonal deficits, and complications of surgery and chemotherapy. A neurologic predictor scale has been developed to quantify the influence of the various tumor- and treatment-related risks for neurocognitive problems. Radiologic evaluation of patients treated for medulloblastoma with craniospinal irradiation, with or without chemotherapy, showed reduced volumes of normal white matter, which correlated with full-scale IQ. Neurocognitive problems are more likely in children treated at a young age or with high doses of radiation, especially when applied to cerebral-cortical areas associated with higher functions. The effects may be progressive for years and may include attention deficit, impaired memory, and lowering IQ. In one series, mean observed full-scale IQ was 97.1 for nonirradiated patients and 78.8 for irradiated patients. For children with standard-risk medulloblastoma, hyperfractionated radiotherapy was associated with better executive function than standard radiotherapy without any difference in behavior or quality of life. These children generally require psychological intervention and special education programs.

Chronic neurotoxicity of chemotherapy used in treating CNS tumors includes hearing loss (eg, especially after cisplatin therapy) and peripheral neuropathy (eg, with vincristine or occasionally cisplatin and etoposide). Renal impairment and hypertension are associated with cisplatin therapy. Osteopenia is found in half of the children surviving brain tumors, and bone pain may limit physical activity. Chemotherapy may potentiate the deleterious effect of craniospinal irradiation on growth.

Secondary Malignancies

There is an increased risk (3%-5%) of second tumors, including meningiomas and sarcomas arising 10 to 20 years after cranial irradiation. Secondary leukemia has been reported after chemotherapy with alkylating agents and etoposide. In a cohort of patients surviving 5 years from diagnosis of a CNS tumor, survival estimates were 91% at 10 years and 86% at 15 years; causes of late mortality were disease progression (58%), second malignant tumor (21%), and medical complications (18%). Among 5-year survivors treated between 1973 and 1998, the risk of second malignant neoplasms was higher for patients treated after 1985, even controlling for radiotherapy, possibly consistent with increased use of intensive chemotherapy in recent years. A subsequent report refuted this conclusion, showing that the risk of second neoplasm was no higher following radiotherapy plus chemotherapy than following radiotherapy alone (12.0% vs 11.3%, respectively, at 20 years in medulloblastoma patients).

151 Pediatric Brain Injury and Shaken Baby Syndrome

Joshua Cappell and Steven G. Kernie

KEY POINTS

1. Pediatric brain injury includes a broad array of clinical presentations, which further vary within the childhood age spectrum.
2. Causes are socially influenced and include child abuse, self or mutual violence, vehicular, firearm use, and high-risk behaviors of adolescence.
3. Primary brain injuries reflect velocity, mechanism, biomechanical factors, and compartment involved.
4. Secondary brain injuries reflect macroscopic/structural and microscopic/metabolic sequelae of the initial injury.
5. Imaging criteria for traumatic brain injury (TBI) have meaningfully reduced unnecessary exposure to ionizing radiation, particularly in mild TBI.
6. Medical management is directed toward secondary prevention; few modalities are available to promote reversal of injury.
7. Prognostication in pediatric TBI remains challenging across the spectrum of disease.
8. Long-term management often includes neurologic care given risk of seizures as well as comprehensive academic planning.

INTRODUCTION

The still-developing nervous system holds the potential for greater recovery from traumatic brain injury (TBI) while also carrying the risk of disordered development, dysplasia, and other adverse sequelae. At the same time, mechanical factors may differentiate pediatric from adult injury such as the unfused or less mineralized calvarium and the narrower subarachnoid and sulcal spaces. Pediatric head trauma also differs not only from adult but also within the childhood age spectrum. The mechanisms, including not only the velocity but also the *intentionality*—whether the injury was accidental—strongly affect the severity distribution. Greater impact force, as seen in vehicular (especially unrestrained)-induced injury or nonaccidental injury, skews the distribution toward more severe presentation and worse outcomes.

Data gleaned from the large American ADAPT (Approaches and Decisions in Acute Pediatric TBI) trial, an interinstitutional comparative effectiveness study, has confirmed that seizures and apneas are more common in the abusive head trauma patients when compared with other mechanisms.

EPIDEMIOLOGY

Trauma is the major cause of morbidity and mortality in childhood, and nervous system involvement is the biggest determinant of severity. Children account for about one-half million incidents of TBI per year in the United States, a rate disproportionately high for their part of the overall population. Although the mechanisms and circumstances vary across the pediatric age range—with child abuse dominant in infancy and self- or mutual violence, vehicular, firearm use, and other high-risk behaviors prevalent in adolescence—it remains true across the pediatric age range that the causes are to a great extent socially influenced rather than purely sporadic and therefore often at least potentially preventable. As such, the reduction of the immense toll of brain injury relies on two distinct approaches: prevention of primary injury and of secondary injury.

The former is an educational and legal as much as medical task. Initiatives such as infant car seats, bike helmets, and statewide abuse recognition and reporting systems are critical components. Although recent public attention to cumulative and late effects of concussion was largely generated by cases of prominent adult athletes, much of the response has been to change practice from middle school through college, the duration of the athletic careers of most of the public.

PATHOBIOLOGY

Primary Brain Injury

The pathophysiology of primary and secondary brain injury is distinct (Fig. 151.1). The primary injury depends on linear and angular velocity, mechanism (penetrating or closed), biomechanical factors (contrecoup injury), trajectory, and compartment. The consequences can be considered based on the tissue impacted. Epidural and subdural bleeds (Fig. 151.2) contribute to injury largely due to the pressure they cause by stealing intracranial space. Gray matter architecture can be disrupted in concussion, contusion, or abrasion. Cortical projections and corticocortical connections can be interrupted by penetrating foreign bodies or bone fragments. Less obvious on initial computed tomography (CT) imaging but highly influential on outcome is the diffuse axonal injury, the shearing of fiber tracts from torsional forces. Cerebral ischemia due to vascular dissection, occlusion, and thrombosis can be as injurious as force to the parenchyma directly. In intentionally inflicted trauma, multiple mechanisms may have contributed. The injuries of the "shaken baby" can be compounded by impact, partial strangulation, or carotid compression.

(From Mattiello JA, Munz M. Four types of acute post-traumatic intracranial hemorrhage. *N Engl J Med*. 2001;344[8]:580.)

Secondary Brain Injury

Secondary injury encompasses all subsequent deleterious processes at various levels of organization (Table 151.1).

Macroscopic Secondary Injury

On a macroscopic scale, the pediatric brain is at high risk from loss of volume. Because brain growth drives skull growth in childhood and the atrophy of adulthood is not yet present, accommodation of hematoma and cerebral edema (which evolves largely over the first 3 days postinjury) is poor. Although the dura and unfused calvarium of the neonate and infant flexibly allows reshaping (as required during parturition), it maintains intracranial volume nearly constant as it is inelastic to outward stretch. Consequently, babies too are subject to severe restriction of the intracranial vault. Pressure can cause herniation, compromise cerebral perfusion pressure globally, or compress adjacent cerebral vessels exacerbating tissue compromise.

Multiple factors threaten the already wounded cortical tissue. Cerebral autoregulation is less robust after injury, increasing the risk that cerebral perfusion pressure will fall beneath the compensated range. Injury to the normally well-sealed and precisely regulated blood-brain barrier implies loss of control of the neuronal microenvironment.

Microscopic Secondary Injury

At the cellular level, excitotoxicity due to excessive glutamate release, calcium entry, and hyperactivated intrinsic membrane conductances place increased metabolic demands and interfere with cell volume regulation. At the same time, mitochondrial dysfunction and impaired perfusion make the cells less able to meet these increased demands, leading to cell death.

TABLE 151.1 Example Mechanisms of Secondary Brain Injury after Trauma

Systemic
Hypoperfusion due to the following:
• Respiratory cause: hypoventilation, airway obstruction, lung injury
• Cardiac causes: commotio cordis, stunned myocardium, arrhythmia
• Vascular cause: hypotension due to hemorrhagic hypovolemia, spinal shock, adrenal injury or insufficiency, dysautonomia, especially associated with delirium
• Electrolyte abnormalities of central cause but with systemic effect (salt wasting, diabetes insipidus, syndrome of inappropriate antidiuretic hormone secretion)
Intracranial
• Hypoperfusion due to expanding mass
• Subdural, epidural, parenchymal hematoma (which can be due to loss of clotting factors to systemic injury), hydrocephalus, or swelling of diffuse axonal injury
• Excitotoxicity and energy exhaustion due to seizures
Injury to Intervening and Adjacent Structures
• Carotid occlusion or dissection, poor jugular drainage
• Infection due to penetrating injury, of particular concern with injury to the sinuses

Although overlapping with mechanisms of secondary injury in the adult, the distribution of injury may differ in the child because of incomplete myelination and selective expression of transmitter and voltage-dependent conductance in specific developmental windows.

DIAGNOSIS AND MANAGEMENT

Medical management is directed toward secondary prevention, providing, through optimized care, the best possible outcome obtainable given that an injury has already occurred. This is the medical challenge commonly faced by practitioners in a chain from the first responder to the emergency room and the pediatric intensive care unit. To date, few modalities are available to promote reversal of injury, and neuroprotection in the strictest sense, of physiologically isolating the brain from systemic changes, remains largely experimental. Consequently, the focus of management in the acute period is on preventing additional injury so that the body may gradually heal itself to the maximum extent to which it is intrinsically capable rather than extrinsically promoting healing.

The mechanisms of potential secondary injury to be intercepted are several: Head trauma is often accompanied by systemic trauma. This in turn can cause brain hypoperfusion at the very moment that the brain is most susceptible to hypoperfusion due to impairment of the usual protective reflexes that ordinarily prioritize the maintenance of cerebral blood flow. Consequently, the highest priority in the acute management of pediatric brain injury is on stabilizing perfusion: providing adequate oxygenation, ventilation, and blood pressure. Hypotension in particular is common due to many mechanisms (see Table 151.1) and has been shown to be quite deleterious, independent of other factors. It should be combatted aggressively by fluid resuscitation and, as needed, by pressor support and transfusion.

Differences between pediatric and adult TBI are emphasized by improved outcomes when children are treated at pediatric-experienced centers. Direct admission to such a center is superior to secondary transfer.

Although the perception of some practitioners may be that highly specialized elective procedures or workups mandate tertiary care, whereas trauma is the "bread and butter" of community hospitals, studies show to the contrary that not only is trauma experience important but also pediatric-specific experience in particular matters in childhood injury.

As in all cases of pediatric trauma, clinicians must always consider whether the child presenting with TBI has injuries consistent—in both severity and wound age—with the reported mechanism. Infants are most vulnerable both because they are affected at higher rates and because they are unable to recount events. Difficult legal and ethical questions arise often because many traumas result from poor supervision, raising concern for negligence even when there was no intent to harm. In inadequately explained trauma, a social or home safety screening, involvement of child protection specialist, and discussion with the jurisdictional agency are imperative. Screenings are mandated whenever even a concern has been raised by a presentation not only when there is a high suspicion or certainty. As such, it is most constructive for parents to regard reporting as a chance to assess and mitigate risks rather than an accusation, much less a determination, of criminality. Workup is directed both toward uncovering other signs of abuse as well as ruling out disorders that may actually present similarly or be claimed as such. Although recent work argued against von Willebrand disease being a mimic of abuse, for example, excluding a bleeding diathesis can still be of medicolegal importance

Factors to be considered are shown in Table 151.2.

Minor Traumatic Brain Injury

Patients presenting with a Glasgow Coma Scale (GCS) score of 8 or less (see Table 47.3) are defined by most studies as having severe head trauma. Patients with a GCS of 14 or 15 are generally regarded as having minor head trauma. This category often overlaps with concussion, defined as a head injury causing transient loss or alteration of consciousness or loss of memory. Increasing evidence that lasting encephalopathy can result from the cumulative effects of even minor head trauma in professional sports has made this a source of greater societal and parental concern. American Academy of Neurology guidelines recommend refraining from activities with recurrent injury risk (practice or play) until resolution of concussion and associated symptoms such as headache. American Academy of Pediatrics guidelines also recommend "cognitive rest"

TABLE 151.2 Considerations in Evaluation of Possible or Suspected Nonaccidental Trauma

• Establish age of injury or injuries and determination of consistency with reported history.
• Social work screen; discuss with child protective services, police, or district attorney's office
• Ophthalmology consult with dilated examination
• Skeletal survey and/or radionucleotide study for reactive changes of older, healing bone injury
• Exclude (by clinical findings or lab test) other causes such as coagulopathy, osteogenesis imperfecta, or glutaric aciduria.

including reducing academic activities to prevent exacerbation of symptoms. However, there is no evidence supporting this as either necessary or beneficial for recovery.

Indications for Head Computed Tomography Imaging in Minor Traumatic Brain Injury

Several studies have established criteria mandating a head CT in infants and children presenting with injury, aiming to eliminate unnecessary scans while assuring that no potentially actionable findings are missed by not scanning. The Canadian Assessment of Tomography for Childhood Head Injury or "CATCH" rule is to scan any child with any of the following: GCS less than 14, suspected open or depressed skull fracture, worsening headaches, or irritability on exam. Application of this rule identified 98% of patients with CT findings of injury and all patients requiring surgical intervention among the 2,043 CTs performed.

The Pediatric Emergency Care Applied Research Network (PECARN) conducted a large study across 25 centers to identify and validate a decision rule to determine necessity of head CT for children (younger than 18 years) presenting with a GCS of 14 or 15 LEVEL 1.[1] Among children younger than 2 years of age, criteria with predictive value were alteration of mental status per examiner *or* not at baseline per parent, presence of nonfrontal scalp hematoma, loss of consciousness longer than 5 seconds, severe mechanism (vehicular, hit by high-velocity object or >3 ft fall), or palpable fracture. Absence of these elements had a predictive value approaching 100% for excluding clinically important injury warranting CT scanning (**Fig. 151.3**). In the children 2 years or older, validated criteria were any alteration of mental status, *any* loss of consciousness (even <5 s), emesis, severe injury (in these meaning vehicular, high-velocity object or >5 ft fall), signs of basilar skull fracture (Battle or "raccoon" sign, hematotympanum, or cerebrospinal fluid oto- or rhinorrhea), and severe headache. Absence of these factors was greater than 99% predictive for the absence of a clinically significant injury to be found on imaging, providing a level I evidence basis for decision making. A recent survey by the Pediatric Emergency Care Applied Research Network found that adherence to the clinical decision rule can indeed modestly reduce the number of CTs while detecting clinically important TBIs.

Depending on the mechanism of injury, imaging of the neck may be warranted as well and stabilization kept in place until concurrent cervical trauma is excluded. Particularly in cases where there may have been strain or torsion between head and torso, consideration should be given to the possibility of C-spine fractures, subluxations, ligamentous injury, and vessel damage such as carotid or vertebral dissection.

Severe Traumatic Brain Injury

In an effort to improve and standardize the management of severe pediatric TBI, a collaborative literature review was undertaken to assemble evidence-based guidelines. These have recently been updated and are the basis of **Table 151.3**. Regarding some interventions, large, well-designed trials have been performed, for example, showing that cooling did not show a demonstrable neuroprotective benefit in children, or did steroids in a large adult trial. In **Table 151.4**, the order in which interventions are implemented is presented with higher "tiers" offering more aggressive measures for the circumstance that the prior, less invasive tier has failed to adequately control intracranial pressure (ICP). Particular management considerations and evidence are described in the text below.

Intracranial Pressure in Children

Normal ICP in children ranges up to 28 cm H_2O corresponding to 20 mm Hg. Elevations of ICP after trauma have been associated with higher mortality in observational studies, especially if elevated ICP has been unresponsive to interventions. Although ICP monitors have not been directly demonstrated to improve outcomes, they do allow the titration of therapies that reduce ICP. Lower ICP, even when achieved by intervention, correlates with better outcome. Consequently, the latest pediatric TBI guidelines include a level III recommendation for the consideration of ICP monitoring in severe TBI. A recent trial in Bolivia and Ecuador directly comparing management with and without the use of ICP monitoring included some adolescents (age older than 13 years). However, the study was not powered to analyze teenagers separately.

Analysis of data on over 3,000 children treated at 30 hospitals did not find any difference in outcome depending on whether an ICP monitor was placed. However, the monitored group may have been higher risk to begin with in ways inadequately captured by retrospective analysis so that it was benefit of their monitor that brought their outcomes down to that of the unmonitored group.

Hypothermia Following Severe Traumatic Brain Injury

Hypothermia as a treatment modality after TBI was carefully evaluated by the Canadian Critical Care Trials Group in the Hypothermia Pediatric Head Injury Trial LEVEL 2.[2] Two hundred twenty-five children were randomly assigned to either hypothermic therapy 90.5°F, initiated within 8 hours of the injury and maintained for 24 hours, or normothermia. No advantage was found for hypothermia, a level I evidence finding (this and other level I designations in the present chapter are based on criteria comparable to the original version of the pediatric severe TBI guidelines, generally corresponding to level II in the second edition). In fact, more hypotension was seen in the hypothermia group with a possible trend toward greater mortality. Whether there exist individual subgroups, such as refractory elevated ICP awaiting decompression, who may benefit, remains uncertain. Meanwhile, routine use of hypothermia cannot be recommended for pediatric TBI.

Seizure Prophylaxis

The original Temkin et al. study in 1990 established a benefit to the short-term use of phenytoin in patients older than 16 years of age to reduce seizures in the week after injury. Indications for prophylaxis were the presence of intracranial blood and/or a depressed skull fracture LEVEL 1.[3] In a retrospective analysis of pediatric cases, low GCS scores were most predictive of early seizures, and treatment with phenytoin was associated with a lower seizure rate. In one prospective trial, no benefit for rate of seizures within 48 hours was seen in children receiving phenytoin within 1 hour of arrival LEVEL 1.[4] However, benzodiazepines given for elevated ICP or intubation may have masked the effect. The current pediatric TBI guidelines include a level II recommendation for consideration of phenytoin prophylaxis. Since the introduction of intravenous levetiracetam, this is an increasingly chosen option because of a perceived high degree of efficacy and a favorable side effect profile. The feasibility of this was demonstrated by a phase II trial in 2013 in which levetiracetam 55 mg/kg/d, divided twice a day, was administered to children ages 6 to 17 years for 30 days. A prospective trial will be needed to confirm benefit.

FIGURE 151.3 Suggested computed time (CT) algorithm for children younger than 2 years **(A)** and for those aged 2 years and older **(B)** with Glasgow Coma Scale (GCS) scores of 14 to 15 after head trauma. Abbreviations: ciTBI, clinically important traumatic brain injury; LOC, loss of consciousness. *Data are from the combined derivation and validation populations. †Other signs of altered mental status: agitation, somnolence, repetitive questioning, or slow response to verbal communication. ‡Severe mechanism of injury: motor vehicle crash with patient ejection, death of another passenger, or rollover; pedestrian or bicyclist without helmet struck by a motorized vehicle; falls of more than 0.9 m (3 ft) (or more than 1.5 m [5 ft] for panel B); or head struck by a high-impact object. §Patients with certain isolated findings (ie, with no other findings suggestive of traumatic brain injury), such as isolated LOC, isolated headache, isolated vomiting, and certain types of isolated scalp hematomas in infants older than 3 months, have a risk of ciTBI substantially lower than 1%. ¶Risk of ciTBI exceedingly low, generally lower than risk of CT-induced malignancies. Therefore, CT scans are not indicated for most patients in this group.

Repeat Imaging

Criteria for repetition of imaging in pediatric TBI are not well established. In one analysis, worsening was found in 13% of follow-up scans. However, among these, all requiring surgical intervention had clinical indications of worsening neurologic status. Consequently, the pediatric TBI guidelines include a level II recommendation suggesting that repeat imaging may not be warranted in the absence of clinical change or increasing ICP. On the other hand, in a separate large retrospective case series, 27% of patients showed worsening, of whom less than a fifth had accompanying clinical signs. Furthermore, among those whose CTs led to surgical intervention, two-thirds did not have clinical signs. This would suggest that high clinical concern based on initial findings or clinical picture in addition to worsening or rising ICP is sufficient justification for repeat CT.

TABLE 151.3 Best Evidence Management for Severe Traumatic Brain Injury[a,b]

Invasive Pressure Monitoring
Use of ICP monitoring is suggested in infants with severe TBI (level III).
Intracranial Pressure
Treatment of ICP is suggested at targeting a threshold of <20 mm Hg (level III).
Cerebral Perfusion Pressure
A CPP threshold of 40-50 mm Hg is suggested to ensure that the minimum value of 40 mm Hg not be breached. There may be age-specific thresholds with infants at the lower end and adolescents at the higher end of this range (level III).
Advanced Neuromonitoring
If brain oxygenation monitoring is used, maintenance of a partial pressure of brain tissue oxygen >10 mm Hg is suggested (level III).
Hypothermia
Prophylactic moderate (32°C-33°C) is not recommended over normothermia to improve overall outcomes (level II). Moderate hypothermia (32°C-33°C) is suggested for ICP control (level III).
Ventilation
Prophylactic severe hypoventilation to a $Paco_2$<30 mm Hg in the initial 48 h after injury is not suggested (level III). If hyperventilation is used in the management of refractory intracranial hypertension, advanced neuromonitoring for evaluation of cerebral ischemia is suggested.
Seizure Prophylaxis
Prophylactic treatment is suggested to reduce the occurrence of posttraumatic epilepsy (level III).
Use of Steroids
The use of steroids is not suggested to improve outcome or reduce ICP (level III).
Sedatives
With use of multiple ICP-related therapies as well as appropriate use of analgesia and sedation in routine ICU care, avoiding bolus administration of midazolam and/or fentanyl during ICP crises is suggested due to risks of cerebral hypoperfusion (level III).
Reimaging
Excluding the possibility of elevated ICP on the basis of a normal initial (0-6 h after injury) CT examination of the brain is not suggested in comatose pediatric patients (level III). Routinely obtaining a repeat CT scan >24 h after admission and initial follow-up is not suggested for decisions about neurosurgical intervention, unless there is either evidence of neurologic deterioration or increasing ICP.
Hyperosmolar Therapy
Bolus hypertonic saline (3%) is recommended in patients with intracranial hypertension. Recommended doses for acute use range between 2 and 5 mL/kg over 10-20 min (level II). Continuous infusion of hypertonic saline is suggested in patients with intracranial hypertension. Suggested effective doses as a continuous infusion of 3% saline range between 0.1 and 1.0 mL/kg of body weight per hour, administered on a sliding scale. The minimum dose needed to maintain ICP <20 mm Hg is suggested (level III). Bolus of 23.4% hypertonic saline is suggested for refractory ICP. The suggested dose is 0.5 mL/kg with a maximum of 30 mL (level III).

TABLE 151.4 Stepwise Approach to Management of Elevated Intracranial Pressure

Tier 1
• Head of bed elevation • Sedation and neuromuscular blockade • Mechanical ventilation to normal arterial carbon dioxide pressure • Active normothermia • Hyperosmolar therapy • External ventricular drainage
Tier 2
• Moderate hyperventilation • Mild hypothermia (to 35°C) • Thiopental infusion
Tier 3
• Decompressive craniectomy

Decompressive Craniectomy

The recent DEcompressive CRAniectomy (DECRA) trial, which did not show a survival benefit to decompressive craniectomy as a rescue therapy, did not include children. A prospective but small, early pediatric trial found a trend toward benefit of decompressive bitemporal craniectomy in patients with medically refractory ICP. However, the decompression in this study was performed without duraplasty, different from the techniques more commonly employed. A larger study in children including duraplasty has yet to be done, and the use of decompressive craniectomy including duraplasty is regarded as a level III option in the pediatric TBI guidelines.

OUTCOME

Except in the most severe of cases, the degree of injury, whether by clinical criteria or imaging, incompletely predicts ultimate outcome. Consequently, prognostic prediction during the acute treatment should be cautious. In children, recovery may continue long after the injury. Diffusion tensor imaging is emerging as the best predictor, especially for the extent of white matter damage in diffuse axonal injury. There is less clinical experience with the use of serum markers for gradation in trauma.

Patients with moderate and severe injuries typically will require inpatient rehabilitation after their stabilization. Impairments of gross and fine motor skills are easily identified and readily justify the need for physical and occupational therapy. However, parents should be forewarned of the possibility of more subtle deficits that may even be unapparent on screening neurologic exam but can impose large burdens as the patient attempts to resume activities of daily living and education. Posttraumatic changes in memory, attention, motivation, as well as migraine or tension-like headaches can all interfere with return to school. Neuropsychological testing can be helpful in identifying cognitive disabilities. Schools can be asked to structure an individualized education plan or supplemental services and accommodation (commonly known as a *504 plan*, referring to Section 504 of Federal Disability Law) to smooth the transition.

Neurologic follow-up may be warranted to treat sequela such as headaches or chronic posttraumatic seizures. Also, in infants, screening may be needed to identify failure of proper skull healing. The incompletely fused or partially mineralized pediatric skull can undergo aberrant healing. Pressure on a fracture or diastasis

of an existing suture can lead to a "growing fracture." Over a period of weeks to months, this can allow formation of so-called leptomeningeal cysts, a misnomer used to describe what is actually a dural herniation through the skull defect. This entity, extremely rare in adults, can be ruled out in young children with severe TBI by a follow-up skull film 6 weeks to 3 months after injury.

152 Human Immunodeficiency Virus, Fetal Alcohol Syndrome, and Drug Effects

Claudia A. Chiriboga

KEY POINTS

1. Although rare in the United States, pediatric human immunodeficiency virus (HIV) affects nearly 1.8 million children ages 0 to 14 years worldwide.
2. Pediatric HIV/AIDS manifestations are broad; depend on severity of underlying HIV and immune response; and can include HIV encephalopathy, stroke, and opportunistic infections.
3. Fetal alcohol exposure is associated with a range of neurologic complications, with a spectrum of severities and phenotypes.
4. The four main neurologic phenotypes following fetal alcohol exposure are fetal alcohol syndrome, partial fetal alcohol syndrome, alcohol-related neurodevelopmental disorder, and alcohol-related birth defects.
5. Prenatal cocaine exposure is associated with neurobehavioral and developmental outcomes, strokes, and malformations.
6. Prenatal opiate exposure is associated with lower intelligence and withdrawal.

PEDIATRIC AIDS AND HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Introduction

With the advent of effective therapy, there have been marked declines in pediatric human immunodeficiency virus (HIV) in some but not all populations. Similar to adult populations, manifestations of HIV infection are broad and relate to the burden of viral load and immune response. Pediatric neurologic sequelae of HIV also relate to severity of illness and can reflect diffuse or focal brain disease, with or without opportunistic infections (OIs).

Epidemiology

Pediatric HIV in the United States continues to decline in children under age 13 years. Unfortunately, worldwide, there are about 1.8 million HIV-infected children aged 0 to 14 years. Most of these children live in Africa, primarily Eastern and Southern Africa, and are infected perinatally. In the United States intravenous drug abuse and sexual contact with HIV-infected partners are the maternal risk factors in nearly all perinatal cases. Mother-to-child HIV transmission rates have dropped dramatically in the United States with the increase in surveillance efforts to identify HIV infection among pregnant women and the use of highly active antiretroviral drugs treatment (HAART) during pregnancy. Perinatal transmission rates in the United States dropped from about 25% prior to prophylaxis to less than 2% with HAART. In 2016, 73 children younger than the age of 13 years were diagnosed with HIV in the United States, a decrease from 166 children diagnosed in 2009. Rates of perinatally acquired HIV in 2015 decreased to less than 1 in 100,000 births in some ethnic/racial groups (white and Hispanic) but remained elevated among African Americans (5.4 per 100,000).

Most HIV transmission from mother to infant occurs in the last trimester of pregnancy and at the time of delivery. Risk factors for vertical transmission are HIV identification at delivery, recent maternal HIV seroconversion, high viral burden, and maternal AIDS LEVEL 1.[1] Premature infants are also at increased risk of infection. Infection may result from exposure to blood and other body fluids at delivery. Breastfeeding is, thus, not recommended in the United States; cesarean section is not routinely recommended unless maternal viral burden is high. Youths (older than age 13 y and younger than age 24 y) are the fastest growing group of HIV-infected individuals and in 2017 accounted for 21% of new HIV diagnoses most increase occurred in the 21 to 24 years age range. HIV infection predominantly affected adolescent and young men (87%) and were mostly the result of male-to-male sexual transmission. Heterosexual contact is the main risk factor for adolescent girls and young women.

Determining transmission of HIV infection to offspring based on detection of HIV antibody has been replaced by infant HIV polymerase chain reaction (PCR). Furthermore, maternal HIV infection status is no longer required to determine infant HIV infection status. The Centers for Disease Control and Prevention surveillance definition states a child is considered definitively infected if he or she has positive virologic results on two separate specimens or is aged older than 18 months and has either a positive virologic test or a positive confirmed HIV antibody test. HIV-seropositive children who do not meet these criteria are considered perinatally exposed and later seroreverters when antibodies turn negative. Since 1994, clinical classification system for confirmed cases of HIV infection in children has been replaced by a five staging system that applies to both adults and children: 0, 1, 2, 3, or unknown. Stage 0 corresponds to early infection as noted by a negative HIV test within 6 months of HIV diagnosis. Stages 1 to 3 are classified immunologically (absolute CD4 count or percent CD4 count) depending on the child's age (younger than 12 mo, 1-5 y, and older than 6 y): stage 1, no evidence of immune suppression; stage 2, moderate immune suppression; and stage 3, severe immune suppression (either a low CD4 count or whether an

TABLE 152.1 Infection Stage Based on Age-Specific CD4⁺ T-lymphocytes Count or Age-Specific CD4⁺ T-lymphocyte Percentage of Total Lymphocytes[a]

		<12 mo		1-5 y		>6 y	
Stage	Immunologic Category	Cells/μL	(%)	Cells/μL	(%)	Cells/μL	(%)
1	No evidence of suppression	≥1,500	(≥34)	≥1,000	(≥30)	≥500	(>26)
2	Moderate suppression	750-1,499	(26-33)	500-999	(22-29)	200-499	(14-25)
3	Severe suppression	<750	(<26)	<500	(<22)	<200	(<14)

opportunistic illness was diagnosed) (Table 152.1). T-cell counts in infants and toddlers are higher for a specific immune category and reach adult levels after age 6 years.

Pathobiology

HIV infection is maintained by viral persistence in helper T lymphocytes and macrophages. HIV strains with tropism for monocyte-derived macrophages have a predilection to infect cerebral vascular endothelium and the central nervous system (CNS). Infected macrophages traverse the blood-brain barrier and infect microglial cells; astrocytes are infected nonproductively, whereas neurons are spared from direct infestation. Neuronal dropout is seen as the disease advances, but it is not known how HIV induces neural damage. Postulated mechanisms include release of soluble neurotoxins by HIV-infected macrophages and lymphocytes (eg, cytokines, quinolinic acid, viral antigens, or undefined viral products), neurotoxin amplification by astrocyte-macrophage interaction, and impaired blood-brain barrier function secondary to HIV-related endothelial damage. Nonproductive infection of a portion of astrocytes is reportedly amplified bystander neurotoxicity. These neurotoxins are believed to produce a reversible metabolic encephalopathy that may disappear with effective antiretroviral treatment.

Glial nodules and endothelial hyperplasia with calcification, dystrophic calcification, and perivascular mononuclear inflammation are common pathologic findings of subacute encephalitis in HIV-infected brains. The glial nodule comprises a cluster of chronic inflammatory cells in the neuropil and is often associated with multinucleated giant cells, which presumably arise from coalescent microglia.

Clinical Manifestations

Mild HIV infection includes diarrhea, unexplained persistent fever, lymphadenopathy, and parotitis. Lymphoid interstitial pneumonitis and recurrent bacterial infections are seen in HIV-infected children but not in infected adults. Prior to the advent of antiretroviral therapy, severe manifestations in early infancy, such as progressive encephalopathy or OIs (eg, *Pneumocystis jiroveci*, formerly known as *Pneumocystis carinii*), carried a poor prognosis for survival, but with effective antiretroviral therapy, these disorders are compatible with survival to adulthood.

Human Immunodeficiency Virus Encephalopathy

Two types of encephalopathy are seen in children: progressive and static. The evolution of the progressive encephalopathy may be fulminant, inexorably progressive, or stepwise. Progressive encephalopathy is characterized by loss of developmental milestones, progressive pyramidal tract dysfunction, and acquired microcephaly or impaired brain growth. The static encephalopathy is less well defined, and all cases may not be related to direct HIV CNS disease.

The neurologic abnormalities commonly include abnormalities of muscle tone, hyperreflexia, clonus, and impaired head growth. Hypotonia with corticospinal tract dysfunction may be seen in infants early in the course of the encephalopathy and evolves into a spastic diparesis; with newer antiretroviral treatments, progression to a spastic tetraparesis, with or without pseudobulbar palsy, is seldom seen in the United States. In Jamaica, 23% of HIV-infected children presenting between 2002 and 2009 had a diagnosis of HIV encephalopathy, a third of whom had a spastic tetraparesis. Ataxia and rigidity are uncommon. Prior to HAART, progressive neurologic dysfunction was the first evidence of progression to AIDS in 10% of infected children. In young children, early presentation may mimic a leukodystrophy. At the time of neurologic symptom onset, there is always evidence of underlying HIV infection, such as immunologic compromise (low CD4 counts) or high viral load. Many infected children exhibit global developmental delay or cognitive impairment of varying degree regardless of neurologic findings.

The rate of neurologic abnormalities reported in HIV-infected cohorts before the advent of antiretroviral treatments was 15% to 30%. The incidence of progressive HIV encephalopathy in 2000 was less than 2% in the U.S. cohort followed. Children most at risk are those who have recovered from HIV encephalopathy. Older HIV-infected children may show problems in visual-spatial processing functions and expressive language and may develop AIDS dementia complex indistinguishable from that described in adults. Children with HIV encephalopathy who respond to antiretroviral therapy may show reversal of microcephaly and cognitive impairments. The most frequent sequelae of "arrested" HIV encephalopathy are learning difficulty and nonprogressive mild spastic diparesis.

Primary Central Nervous System Lymphoma

HIV is associated primary CNS lymphoma (non-Hodgkin), which is an AIDS-defining condition. The rate of this mostly B-cell lymphoma is 2% to 6%, 1,000 times higher than in the general population and mostly linked to Epstein-Barr virus infection. The incidence of CNS lymphoma has decreased because the advent of HAART from an incidence ratio (HIV-infected children/uninfected children) of 1,994 down to an incidence ratio of 1,088. CNS lymphoma is still the most common cause of focal cerebral signs in symptomatic HIV-infected children (see also Chapter 103). It is often multifocal, and seizures are reported

TABLE 152.2 Distinguishing Features Between Central Nervous System Lymphoma and Toxoplasmosis Abscess

	Lymphoma	Toxoplasmosis
Distribution of lesion	Often solitary, subependymal spread	Typically multifocal, basal ganglia or cortico-medullary junction
Enhancement	Typically homogenous	Often ring or nodular
MR perfusion	Increased rCBV	Decreased rCBV
SPECT	Increased uptake	Decreased uptake
MRS	Increased choline peak	Decreased choline peak

Abbreviations: MR, magnetic resonance; MRS, magnetic resonance spectroscopy; rCBV, relative cerebral blood volume; SPECT, single-photon emission computed tomography (thallium).

in about 33% of patients. It may be difficult to differentiate this tumor from a toxoplasmic brain abscess by neuroimaging, but a positive PCR for Epstein-Barr virus in cerebrospinal fluid (CSF) is highly suggestive of CNS lymphoma. Thallium single-photon emission computed tomography and magnetic resonance (MR) spectroscopy may prove helpful in distinguishing CNS toxoplasmosis from lymphoma (Table 152.2). Diagnostic confirmation may require brain biopsy.

Stroke

Untreated HIV infection produces inflammation of cerebral vessels, increasing the risk of stroke, which occurred at a rate of 1.3% a year in symptomatic HIV-infected children. More than 50% of strokes were hemorrhagic and occurred with thrombocytopenia (especially immune thrombocytopenic purpura) or CNS neoplasia. Nonhemorrhagic stroke and subarachnoid hemorrhage are attributed to an arteriopathy of large vessels in the circle of Willis (fusiform aneurysms) or meninges (Fig. 152.1). HIV-related strokes may be clinically silent, so the true incidence is probably higher. In cases of stroke, varicella-zoster virus (VZV) should be excluded as the etiologic agent by CSF PCR, especially when small intracranial vessels are involved. Ocular involvement should be excluded by pupillary dilatation for ophthalmologic assessment. Any vasculopathy in an HIV-infected patient is presumed to be infectious (from either HIV or VZV) and should be treated with appropriate antiretroviral and antiviral medication.

FIGURE 152.1 Fusiform aneurysm in a child with advanced human immunodeficiency virus encephalopathy presenting with intraventricular hemorrhage and stroke.

Opportunistic Central Nervous System Infection

As opposed to adults, OIs in children involve primary infections rather than reactivation. Exposure rates to OI pathogens are cumulative and approximate adult rates by adolescence. Hence, rates of CNS OI occur less frequently in HIV-infected young children. Presentation and treatment of OIs are akin to what is described among HIV-infected adults (see Chapter 70). For instance, the seroprevalence of the John Cunningham virus that causes progressive multifocal leukoencephalopathy (PML) rises from about 16% in children 1 to 5 years of age to 34% by age 21 to 50 years. Prior to HAART, the PML event rate was 0.06 per 100 person years, with affected children identified at a median age of 10.8 years and median CD4 count of 6 cells/mm^3. Survival of children with PML has increased with antiretroviral treatment and effective antiretroviral combination therapy.

Less Common Manifestations

HIV-associated myelopathy, polyneuropathy, and myopathy are rare in children. Spinal cord pathology may show demyelinating changes of the corticospinal tracts, vacuolar changes, or myelitis attributable to HIV or other virus. Acute inflammatory demyelinating polyneuropathy is a rare complication in pediatric HIV.

HIV brain infection is nonfocal and subcortical. Seizures are not common. Focal signs or seizures raise the possibility of neoplasm, strokes, or, less likely, OIs.

Diagnostic Testing

Human Immunodeficiency Virus Testing

Because of early testing, most HIV-positive children in the United States are identified soon after birth, especially in states with universal perinatal screening. HIV DNA PCR is the preferred diagnostic method, whereas quantitative HIV RNA PCR is more sensitive in determining plasma concentration (copies per mL) of HIV RNA, commonly referred to as *plasma viral load*. By age 6 months, 100% of HIV-infected children are identified by a positive PCR. In newborns, a negative PCR test for HIV does not exclude infection but decreases the risk of HIV infection to 3%. Viral load runs higher in asymptomatic children than in asymptomatic adults. Sustained high viral load and low CD4 count predict progression to AIDS. High viral loads in early infancy predict early onset of symptomatic HIV disease but with prophylactic treatment (during pregnancy and for up to 6 wk to newborn postnatally) rates can be lowered to 1%. In industrialized countries, most progression to AIDS in the post-HAART era, is related to nonadherence to HAART of any cause (ie, medical or social), which in turn facilitates development of drug resistance. HIV-1 syncytial-inducing phenotypes that are linked to aggressive early symptomatic disease.

Neuroimaging

In children with HIV encephalopathy, brain atrophy (cortical and subcortical) is the most common imaging abnormality (Fig. 152.2). Periventricular or parietooccipital demyelination can be observed on magnetic resonance imaging (MRI) (Fig. 152.3). Frontal lobe

FIGURE 152.2 Computed tomography scan of an infant with human immunodeficiency virus encephalopathy showing cortical and subcortical atrophy, basal ganglia, and frontal lobe calcifications. (Courtesy of Dr. Ram Kairam.)

or basal ganglia enhancement and calcifications are late manifestations of HIV encephalopathy, best seen on computed tomography (CT), and occur primarily in symptomatic infants (see Fig. 152.2). Imaging findings may be indistinguishable from Aicardi-Goutières syndrome. HIV myelopathy may show a high signal on spinal MRI but is usually normal. Bilateral cerebral lesions may mimic myelopathy and must be excluded with MRI or CT. Lesions of PML are commonly located in the parietooccipital or frontal regions, affecting both periventricular and subcortical white matter. These lesions may be difficult to distinguish from HIV demyelination.

Cerebrospinal Fluid

CSF findings are commonly normal in children with HIV infection. In the absence of OI, CSF analysis in children with progressive encephalopathy may show nonspecific changes of lymphocytic pleocytosis and elevated protein content. Intra–blood-brain barrier synthesis of HIV-specific antibody or antigen detection in CSF has not been useful in predicting encephalopathy. CSF viral load, although not routinely available, may prove useful in determining HIV encephalopathy in children, especially in cases of compartmentalization (ie, a sequestered HIV reservoir in the CNS), in which systemic measures of viral load do not parallel the CNS level of viral replication.

Management

Antiretroviral Therapy

HAART, consisting of a protease inhibitor or a nonnucleoside reverse transcriptase inhibitor administered in combination with nucleoside reverse transcriptase inhibitors, has been reported to suppress viral replication, improve immune function, and decrease AIDS-related death as well as diminish rates of HIV encephalopathy. High systemic viral load tends to predict the development of HIV encephalopathy, whereas CD4 counts tend to predict HIV disease progression primarily from OIs. Children younger than 1 year tend to be at greatest risk for progression and should be treated regardless of symptomatology LEVEL 1.[2] After 12 months, treatment is not indicated if child is asymptomatic or minimally symptomatic. Most antiretroviral agents

FIGURE 152.3 Parietal occipital demyelination on axial fluid-attenuated inversion recovery (A) and coronal T2 (B) images in a child with advanced human immunodeficiency virus encephalopathy and high viral load (RNA human immunodeficiency virus = 1.5 million copies/mL).

have poor CNS penetrance with the exception of zidovudine, nevirapine, stavudine, and abacavir. However, antiretroviral CNS penetration did not impact the treatment response in AIDS dementia complex. Hence, a change in HAART regimen is not recommended based on CNS involvement.

Antiretroviral Therapy Side Effects

Treatment with nucleoside inhibitors of viral reverse transcriptase can alter mitochondrial (mt) function by inhibiting mtDNA polymerase-γ, which is responsible for the replication of mtDNA. Inhibition of mtDNA results in diminished synthesis of respiratory chain enzymes, causing the syndrome of mt depletion. Antiretroviral-induced mt dysfunction in turn is responsible for diverse adverse effects frequently observed in HIV-infected patients. Nonneurologic side effects include hepatic steatosis, lactic acidemia (>2 mmol/L), and lipodystrophy, a disorder characterized by the accumulation of visceral fat, breast adiposity, cervical fat pads, hyperlipidemia, insulin resistance, and fat wasting in face and limbs. Neurologic side effects include myopathy, peripheral neuropathy, and parkinsonism. mt depletion myopathy can be seen in children treated with combination therapy, especially with nucleoside reverse transcriptase inhibitor that has a high affinity to mt polymerase-γ. Low-dose treatment with didanosine causes a painful sensory neuropathy in less than 10% of patients treated. The neuropathy is dose related and usually clears with cessation of treatment. Didanosine, stavudine, and zalcitabine have a high affinity for binding polymerase-γ, whereas zidovudine, abacavir, tenofovir, and lamivudine have a lower affinity for that enzyme. Changing antiretroviral agents usually relieves the symptoms.

Outcome

Many children treated for HIV experience good response and recovery, with HIV becoming a manageable chronic illness because it can be in adults. Immune reconstitution inflammatory syndrome (IRIS) can occur after introduction of HAART and most often is due to worsening or de novo manifestations of OI (clinically or radiographically) or less often of HIV. The syndrome coincides with improving CD4 count and is not caused by treatment failure or a new infection. In a Johns Hopkins cohort, the independent predictors of IRIS in adults were boosted (with ritonavir) protease inhibitor and rapid decline of viral load (>2.5 log). The infection most commonly reported in adult IRIS is cryptococcal meningitis, but PML and HIV dementia have also been reported. PML-IRIS may be distinguished from PML on MRI because of transient enhancement with contrast. In immune-suppressed (ie, CD4 <15%) Thai children, the incidence of IRIS following HAART was 19%, the median time of onset was 4 weeks, and the primary pathogens involved were VZV and tuberculosis. Most cases of IRIS occur within the first 3 months of treatment, although delayed cases are reported.

FETAL ALCOHOL SPECTRUM DISORDERS

Introduction

The term *fetal alcohol spectrum disorder* was coined to describe the continuum of alcohol effects on the fetus. Ranging from severe to mild, the expanded phenotype associated with prenatal alcohol exposure is composed of four diagnostic categories: fetal alcohol syndrome (FAS), partial fetal alcohol syndrome, alcohol-related neurodevelopmental disorder, and alcohol-related birth defects (Table 152.3). Current definition of documented prenatal alcohol exposure includes greater than or equal to 6 drinks a week or greater than or equal to 3 drinks per occasion greater than or equal to 2 occasions during pregnancy, social or legal alcohol-related problems, acute intoxication, or positive alcohol biomarker during pregnancy. Fetal susceptibility to the effects of alcohol is greatest during the first trimester of pregnancy, but there is no safe trimester to drink alcohol.

TABLE 152.3 Criteria for Diagnosing Fetal Alcohol Spectrum Disorder[a]

Clinical Finding	FAS	PFAS	ARND	ARBD
Dysmorphic features ≥2 of the following: 1. Microphthalmia, short palpebral fissures, or both 2. Poorly developed philtrum 3. Thin upper lip	✓	✓		
Prenatal and postnatal growth impairment (weight or length <10th percentile)	✓	✓[b]		
Structural: head circumference <10th percentile or abnormal brain structure on neuroimaging, unprovoked seizures	✓			
Neurobehavioral deficits • Cognitive impairments >1.5 SD above the norm (>3 y); developmental delay (<3 y) Or • Impaired self-regulation (impaired mood or behavioral or impulse control or ADHD)	✓	✓	✓	
Birth defects associated with prenatal alcohol exposure (clinical or experimental)				✓
Documented prenatal alcohol exposure	NR	NR	✓	✓

Abbreviations: ADHD, attention deficit hyperactivity disorder; ARBD, alcohol-related birth defects; ARND, alcohol-related neurodevelopmental disorder; FAS, fetal alcohol syndrome; NR, not required; PFAS, partial fetal alcohol syndrome; SD, standard deviation.

[a]Adapted from Hoyme HE, Kalberg WO, Elliott AJ, et al. Updated clinical guidelines for diagnosing fetal alcohol spectrum disorders. *Pediatrics*. 2016;138(2):e20154256.

[b]Either one (central nervous system or somatic growth impairment) required when diagnosing without documented prenatal alcohol exposure.

Epidemiology

FAS rates ascertained in a middle-class U.S. community ranged from 6 to 9 per 1,000 children (midpoint, 7.5). The partial fetal alcohol syndrome rate in one community ranged from 11 to 17 per 1,000 children (midpoint, 14). Risk factors for FAS include poverty, poor maternal nutrition, and advanced maternal age.

Pathobiology

Despite extensive study, the specific underlying mechanisms of FAS remain uncertain and suggest a complex process. Risk of FAS is modulated by genetic factors: certain enzyme polymorphisms confer protection (eg, alcohol dehydrogenase enzyme and cytochrome P450 2E1), whereas others increase risk (absence of acetaldehyde dehydrogenase 2 [ADH_2]). Differential diagnosis includes several genetic disorders (eg, velocardiofacial syndrome, William syndrome) and thus warrants genetic testing.

Diagnosis

FAS diagnoses requires two of the three cardinal dysmorphic features affecting (short palpebral fissures [<10th percentile], smooth philtrum, and thin vermilion border of the upper lip), cognitive impairments greater than or equal to 1.5 standard deviation above the mean and growth impairments including small head size or abnormal brain morphogenesis LEVEL 3.[3] Most children with FAS are mildly or moderately retarded, with mean IQ scores of 65 to 70, but intellectual ability varies widely. In families with several affected siblings, the youngest child is usually the most cognitively impaired. Prenatal alcohol exposure has been linked to lower IQ scores, hyperactive behavior, attention problems, learning difficulty (especially with arithmetic), and speech disorders. Neuroimaging abnormalities are common among alcohol-exposed infants and commonly include volume loss/microcephaly and developmental anomalies of cerebellum or corpus callosum (agenesis, hypoplasia). Neuroimaging abnormalities correlate with neurocognitive impairments.

Partial Fetal Alcohol Syndrome

Partial fetal alcohol syndrome is defined based on facial dysmorphology and neuropsychological scores seen in FAS but can be diagnosed with only one of the two growth parameters, either small head circumference or impaired somatic growth.

Alcohol-Related Neurodevelopmental Disorder

Alcohol-related neurodevelopmental disorder requires documented prenatal alcohol exposure and neurobehavioral deficits (either cognitive impairment <1.5 standard deviation above mean in children older than age 3 y), developmental delay (children younger than age 3 y), or impairments of self-regulation (mood or behavioral regulation impairment, attention deficit, or impulse control).

Alcohol-Related Birth Defects and Other Outcomes

Alcohol is a well-established teratogen, and birth defects are common. *Alcohol-related birth defects* refer to isolated birth defects that occurs with documented prenatal alcohol exposure. Anomalies must be linked to alcohol exposure in clinical or experimental settings. Congenital anomalies occur in about a third of infants born to heavy drinkers, compared with 9% of minor anomalies in infants of women who abstain from alcohol (see Table 152.3). Decreasing alcohol intake during pregnancy is beneficial to offspring, reducing the frequency of growth retardation and dysmorphic features.

Maternal alcohol abuse increases the risk of spontaneous abortions, infant mortality, intrauterine growth retardation, and prematurity.

Postnatal Alcohol Exposure

Alcohol transferred through breast milk impairs motor development but not mental development at age 1 year. Ingestion of alcohol by children may lead to hypoglycemic seizures.

Alcohol Withdrawal Syndrome

Infants born to women who drink large amounts of alcohol during pregnancy may rarely exhibit signs of withdrawal. Restlessness, agitation, tremulousness, opisthotonus, and seizures are seen shortly after birth and disappear within a few days.

Management and Outcome

Treatment of FAS is largely supportive, focused on the neurodevelopmental and behavioral challenges these children and their families may face. A comprehensive and supportive approach toward alcohol cessation in the family is important to address other lasting psychosocial impacts of alcoholism on children into young adulthood.

PRENATAL AND PERINATAL EFFECTS OF SUBSTANCE ABUSE

Cocaine

Although the cocaine epidemic has abated, cocaine is still one of the most frequent hard drugs of abuse in urban centers, whereas methamphetamine is the preferred substance of abuse in rural settings (with effects similar to those of cocaine). Cocaine use during pregnancy has been linked to spontaneous abortion, abruptio placentae, stillbirth, and premature delivery. These events may immediately follow a large intake of cocaine and are attributed to drug-induced vasoconstriction of intrauterine vessels. Women who use cocaine tend to resort to prostitution, increasing risks for syphilis and HIV. They also tend to lack prenatal care, adding to the risks of infant death, low birth weight, and prematurity.

Low birth weight and intrauterine growth retardation are common among cocaine-exposed infants. Fetal brain growth is impaired independently of birth weight or gestational age. Sudden infant death syndrome has also been linked to cocaine exposure in utero. In addition to any specific cocaine-related effects, offspring are at increased risk because of polydrug exposure, as cocaine is rarely the only drug used.

Neurobehavior

State regulation difficulties are well described among cocaine-exposed newborns. Findings vary from irritability and excitability to decreased organizational response and interactive behavior, even if the exposure to cocaine was limited to the first trimester of pregnancy. Modulation of attention is impaired among cocaine-exposed infants who, unlike unexposed infants, prefer higher rates of stimuli when in a high level of arousal.

Infant processing abilities, as reflected by looking time at novel stimuli, are also affected by prenatal cocaine exposure. Exposed infants show motor and movement abnormalities, including excessive tremor and hypertonia. Dose-response effects of cocaine on state regulation and neurologic findings that tend to be transient are reported in newborns and infants. Some studies show no neurobehavioral effects, however.

Strokes

Experimentally, cocaine and its main metabolite, benzoylecgonine, cause vasoconstriction of fetal cerebral vessels. Neonatal stroke and porencephaly have been associated with prenatal cocaine exposure. Some cases may be related to other neonatal stroke risk factors that accompany fetal cocaine exposure, such as abruptio placentae or birth asphyxia. Intraventricular hemorrhage is observed among infants more heavily exposed to cocaine.

Seizures

Focal seizures may occur in cocaine-exposed newborns with strokes. Electroencephalograms in cocaine-exposed infants show bursts of sharp waves and spikes that are often multifocal. These findings do not correlate with clinical seizures or neurologic abnormalities and may disappear in 3 to 12 months. Cocaine-exposed premature infants are at increased risk of neonatal seizures. Seizures are rare if there is no stroke.

Malformations

Prenatal cocaine exposure has been linked with urogenital malformations, limb reduction deformities, and intestinal atresia and infarction. Agenesis of the corpus callosum and septo-optic dysplasia has also been noted. These teratogenic effects may result from cocaine-induced vasoconstriction and fetal vascular disruption in early organogenesis.

Neurodevelopmental Impact

In experiment models, prenatal cocaine has been reported to affect serotonin, norepinephrine, dopaminergic, and γ-aminobutyric acid systems. Lower CSF levels of homovanillic acid found in human newborns exposed to cocaine suggest dopaminergic involvement. In infancy, there may be a high incidence of global hypertonia that resolves prior to age 24 months (**Table 152.4**). Many studies in toddlers and school-aged children have failed to show that prenatal cocaine exposure adversely affects cognition, except as mediated through cocaine effects on brain growth. Cocaine-exposed children seem to suffer from language delays and an excess of neurobehavioral abnormalities, including irritability, impaired attention, inhibitory control, impulsivity, and aggressive behavior. Early neurobehavior involving orientation and irritability tend to improve over the first 2 years of life. Heavy prenatal cocaine exposure has been associated with delinquent behavior in both genders at older ages. In children followed through adolescence, low to moderate effects on cognitive, language and behavior (attention, externalizing behaviors, and poor executive function), as well risk for substance misuse are reported.

Cocaine Exposure in Childhood

Passive intoxication with cocaine may be caused by breastfeeding or passive inhalation of free-base cocaine (crack). Seizures are the chief manifestation of symptomatic intoxication but intoxication may be unsuspected. Urine toxicology screening is used to detect illicit substances in evaluating seizures in infants and children, regardless of socioeconomic status.

TABLE 152.4 Neurologic Fetal Cocaine Effects and Associations

Neonatal Period
Microcephaly
Vascular abnormalities
Stroke
Porencephaly
Intraventricular hemorrhage
Seizures
Symptomatic (secondary to vascular complications)
Primary (owing to cocaine or its metabolites)
Brain malformations
Agenesis of corpus callosum

Neurologic
Hypertonia in infancy
Developmental
Language delays
Semantic delays
Behavioral
Inattentiveness
Temperamental differences
Impulsivity
Aggressive or delinquent behavior

Withdrawal Symptoms

There is no evidence of a cocaine-induced withdrawal syndrome. Even with remote prenatal cocaine exposure, cocaine-exposed infants may show hypertonicity and tremor, which are probably manifestations of a transient embryopathy resulting from cocaine-related perturbations of neurotransmitter levels.

Opiates

Cheap and abundant supplies of heroin are fueling a nationwide epidemic of late, especially in urban centers. Prospective studies, however, on the developmental impact of prenatal heroin exposure are sparse. Methadone, on account of its controlled administration, has been more extensively studied. The main risk factor linked to developmental effects and lower IQ scores is the presence of neonatal withdrawal syndrome.

TABLE 152.5 Opiate Withdrawal Syndrome
Central Nervous System
• Jitteriness/tremors
• Irritability
• Hypertonia
• High-pitch cry
• Generalized convulsions
Autonomic
• Fever
• Nasal stuffiness
• Mottling of skin
• Sweating
• Tachypnea
Gastrointestinal
• Vomiting
• Diarrhea
• Poor feeding

Withdrawal Symptoms

Infants born to opiate-dependent mothers (**Table 152.5**) are at risk for neonatal withdrawal syndrome characterized by signs and symptoms of CNS hyperirritability, gastrointestinal dysfunction, respiratory distress, and autonomic disturbances. CNS signs and symptoms consist of hypertonicity, tremor, hyperreflexia, irritability, sleep disturbances, feeding difficulties, and occasionally seizures LEVEL 1.[4] Onset of neonatal withdrawal from heroin usually begins within 24 hours of birth, withdrawal from methadone usually starts around 24 to 72 hours of age, and withdrawal to buprenorphine starts at around 40 hours and peaks in severity at 70 hours of age. The neonatal withdrawal syndrome associated with methadone is more severe and occurs more often (84%) than that described with buprenorphine (60%). For both opioids, signs of withdrawal may be delayed in onset until 5 to 7 days of age or later. Genetic factors may influence onset or severity of withdrawal symptoms. For instance, infants treated for withdrawal were more likely to carry a homozygous allele of the CYP2B6 gene that encodes a cytochrome P450 mono-oxygenase enzyme, whereas certain catechol-o-methyltransferase and μ-opioid receptor single-nucleotide polymorphisms have been linked to more severe withdrawal symptoms. Among neonates acutely withdrawing from opioids, seizures are observed in 2% to 11% and electroencephalogram abnormalities without evidence of seizures in over 30%. Mild withdrawal does not require treatment, other than swaddling and a quiet room, but symptomatic infants are likely to require pharmacologic intervention. The two most popular agents used to treat withdrawal are paregoric (camphorated tincture of opium) and phenobarbital. Of the two, paregoric is more physiologic because it substitutes for the substance causing withdrawal but is only effective for opiate withdrawal. Other opiates studied include morphine and buprenorphine. For suspected polydrug exposure, phenobarbital may be preferable.

The most widespread scale in use to assess the severity of withdrawal syndrome is that developed by Finnegan LEVEL 3.[5]: It assesses 21 signs in three domains: CNS, gastrointestinal, and autonomic/sleep/respiratory. Assessments are recommended every 2 to 4 hours after birth, and treatment is suggested for withdrawal scores 8 or higher. Paregoric or phenobarbital is then titrated according to the severity of withdrawal score. There is no agreed on standard treatment protocol to manage neonatal abstinence. When using phenobarbital, one can choose to load (15 mg/kg) prior to titrating maintenance (5-8 mg/kg) dose. Paregoric doses may start at 0.2 mL every 3 hours and titrate by 0.05 mL according to withdrawal score. Tapering of the dose may commence by the end of the second week as tolerated.

Psychosis 153

Jacob S. Ballon and T. Scott Stroup

KEY POINTS

1. New-onset psychosis requires medical workup to determine possible reversible causes.
2. Delirium is a common cause of psychosis, especially in the elderly or medically compromised.
3. In addition to schizophrenia, psychosis is associated with bipolar disorder, major depression, posttraumatic stress disorder, and delusional disorder.
4. Antipsychotic medications are effective symptomatic treatment of psychosis but are associated with significant adverse effects and should be used judiciously.
5. Clozapine is the only evidence-based medication for treatment-resistant schizophrenia; any decision to discontinue it should be carefully considered.

INTRODUCTION

Psychosis is characterized as a detachment from reality, often including hallucinations or delusions. Psychotic symptoms are a core feature of schizophrenia but may also be seen in other serious psychiatric disorders including bipolar disorder, major depressive disorder, and posttraumatic stress disorder. Importantly, psychosis may also be a prominent symptom in many neurologic disorders, other medical conditions, substance intoxications, and withdrawal syndromes. New-onset psychosis should prompt a thorough workup to determine the etiology of such symptoms.

Psychotic experiences can be characterized as phenomena in which sensory experiences are generated by aberrant brain stimuli rather than external inputs. Hallucinations can be auditory (eg, hearing voices), visual (eg, seeing objects that are not there), or can occur in other sensory domains, although olfactory, tactile, and gustatory hallucinations are less typical of psychiatric illness. Hallucinations can be differentiated from illusions by having no basis in reality, whereas illusions are misperceptions of natural sensations. Delusions are fixed, false beliefs that persist in spite of contradictory evidence. Often, delusions are paranoid (eg, a feeling of being watched or followed) or grandiose (eg, possessing special powers or relationships with powerful people). Hallucinations and delusions must be assessed within the relevant cultural context.

The lifetime prevalence of psychosis is between 3% and 5% in the general population. Most cases of psychosis are due to causes other than schizophrenia. The main causes of nonschizophrenia psychoses are drug-induced psychosis, mood disorders, and general medical conditions.

SCHIZOPHRENIA AND OTHER PSYCHOTIC DISORDERS

Epidemiology

Globally, estimates suggest that almost 1% of the population will develop schizophrenia in their lifetime. The typical age of onset of schizophrenia is the late teens or early 20s, with men diagnosed on average a few years younger than women. Most people who develop schizophrenia have a prodromal period of illness before they meet the threshold for diagnosis. The prodrome is commonly characterized by subthreshold psychotic symptoms in conjunction with declines in social and occupational functioning. Schizophrenia typically follows a relapsing and remitting course characterized by periods of stability with episodic exacerbations of symptoms. Although antipsychotic medications are efficacious in reducing psychotic symptoms, many individuals may still have symptoms despite usual treatment.

Pathobiology

Scientists debate whether schizophrenia is a degenerative brain disease, neurodevelopmental disease, or a combination of both. Several studies have shown that there are neuroanatomic differences in ventricle size, cortical thickness, gray and white matter, and overall brain volume in people with schizophrenia. Supporting neurodevelopmental hypotheses, neuroanatomic differences are seen before the onset of psychosis. However, favoring degenerative hypotheses, these differences increase over the course of illness. Furthermore, although many studies have shown that cognitive decline predates the onset of psychosis, there is some evidence that cognitive deficits worsen over time. It is difficult to isolate a specific degenerative process of schizophrenia itself apart from other environmental factors such as chronic exposure to antipsychotic drugs.

Much work has been done to identify the specific neurotransmitter systems responsible for psychosis and schizophrenia. Although no single system is responsible for the overall psychotic phenotype, several have been shown to contribute to the development of symptoms. Dopamine is often most closely associated with psychosis, and all currently marketed antipsychotic drugs are dopamine D_2 antagonists, but those drugs do not address all facets of the illness. Other neurotransmitters implicated include serotonin, glutamate, and acetylcholine.

Diagnosis

Schizophrenia is a serious mental illness responsible for significant morbidity, diminished quality of life, loss of productivity,

and premature mortality. There is a 5% to 10% risk of suicide, and schizophrenia is a leading cause of disability throughout the world. Symptoms of schizophrenia can be categorized into positive, negative, and cognitive domains. Positive symptoms refer to delusions, hallucinations, and disorganized speech or behavior. Negative symptoms include apathy and avolition and generally refer to deficits in functioning. Cognitive symptoms affect multiple domains including primarily executive functioning, verbal learning, and working memory.

Although schizophrenia cannot be diagnosed until psychosis has been present for at least 1 month, nonspecific symptoms have been seen from early childhood in people who later develop schizophrenia. For example, young children who go on to develop schizophrenia have increased incidence of deficits in motor skills compared to children who do not develop schizophrenia or other psychiatric disorders.

The *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*), which was released in 2013, modified the criteria for psychotic disorders (**Fig. 153.1**). A schizophrenia diagnosis requires at least two out of five symptoms including hallucinations, delusions, disorganized speech, disorganized behavior, or negative symptoms for at least 1 month and with an overall duration of illness of at least 6 months. *DSM-5* requires hallucinations, delusions, or disorganized speech; only having disorganized behavior and negative symptoms does not meet the new criteria. When mood symptoms are prominent, a timeline is essential to determining the correct diagnosis. If there are concurrent mood symptoms along with the hallucinations or delusions, the criteria for schizoaffective disorder are met if the psychotic symptoms persist for at least 2 weeks in the absence of mood symptoms and if the mood symptoms are present for the majority of the entire illness. If the psychotic symptoms occur only in the context of a mood disorder (bipolar disorder or major depressive disorder), then the diagnosis is bipolar disorder or major depressive disorder with psychotic features. If the only psychotic symptom is a delusion, then the diagnosis may be delusional disorder, particularly if there is limited functional impairment. Catatonia is a constellation of psychomotor features that may include stupor, posturing, mutism, stereotypy, and other odd mannerisms. Catatonia is often associated with schizophrenia but can be present in most other serious mental illnesses. Catatonia is included in the *DSM-5* as a specifier for several mental disorders and is seen in approximately 10% of patients hospitalized with schizophrenia.

FIGURE 153.1 Diagnostic algorithm for a patient with psychotic symptoms. (Based on American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Washington, DC: American Psychiatric Association; 2013.)

Bipolar Disorder, Manic With Psychotic Features Case

A 27-year-old recent business-school graduate returned from a trip to Europe and was noted by friends and family to be abnormally active and needing little sleep. In a manner that was distinctly out of character, she purchased a flashy new car and numerous new outfits, the latter usually bought online in the early morning hours. She talked rapidly and extensively about her "unique" entrepreneurial "gifts," and about how she was a "special consultant" to famous e-commerce billionaires. Others were perplexed by her conviction that recent newspaper headlines were intended to communicate her importance. She denied needing to sleep and spent frantic hours trying to "return the calls" of various chief executive officers. When speaking, she spoke rapidly rhymed words and had difficulty getting directly to her point. Despite saying she was in a "fantastic mood" she was often irritable, loud, and angry when confronted about her behavior by friends and colleagues if she didn't get what she wanted immediately. She had no history of delusions or hallucinations.

Major Depressive Disorder With Psychotic Features Case

An 87-year-old woman was admitted to the psychiatric unit with several weeks of depressed mood, social withdrawal from peers, and weight loss of 12 lb. She stated repeatedly that "something is wrong with me" and that her liver was rotting. She was unable to be dissuaded from this belief and perseverated that "everything is hopeless." Once in the hospital, she stayed in her bed all day long and stared at the ceiling. Electroconvulsive therapy was offered and initiated via court order. After four treatments, she began to engage with other patients on the unit for brief periods and to attend group therapy. She continued her course of electroconvulsive therapy along with antidepressant medication and within a month was much improved and seen smiling with her husband.

TABLE 153.1 Distinguishing Characteristics of Illnesses Commonly Associated With Psychosis

Condition	Typical Age of Onset	Distinguishing Characteristics
Schizophrenia	Late teens, 20s; later for women than men	Hallucinations, delusions, disorganized thinking/behavior, and functional impairment
Schizoaffective disorder	Late teens, 20s; later for women than men	Psychotic symptoms are present even in the absence of mood symptoms; mood symptoms are present for the majority of the illness.
Bipolar disorder	20s	Psychosis only in the context of mood episode; typically in context of severe manic episode
Major depressive disorder with psychotic features	Throughout life; peaks 20s and 30s	Psychosis relatively rare; only in the context of depressive episode
Alzheimer disease	Elderly	Present in up to 50% of patients; nonbizarre delusions; visual hallucinations common
Dementia with Lewy bodies	Elderly	Often visual hallucinations; associated with motor symptoms and sensitivity to antipsychotic side effects
Delirium	Throughout lifespan, especially in elderly	Resolves when underlying disturbance has resolved
Posttraumatic stress disorder	Any age; increased risk in veterans	History of severe trauma; predominantly associated with hallucinations, may be associated dissociative symptoms

Psychotic symptoms frequently occur in other psychiatric disorders (Table 153.1). Up to 60% of people with bipolar disorder have a history of at least one psychotic symptom, and psychosis is seen in up to 50% of manic episodes. Psychosis may also be present in depression, especially when it is severe. Overall, people with depression are 3 times more likely to have hallucinations and 9 times more likely to have delusions compared to those without depression. Up to 15% of people with schizophrenia have comorbid obsessive-compulsive symptoms. People with social phobia and general anxiety also have an increased incidence of psychosis. Data from the National Comorbidity Survey suggests that psychosis should lead to a separate subtype categorization of posttraumatic stress disorder and a subtype of "with dissociative symptoms" was added to *DSM-5*. Substance abuse and schizophrenia frequently co-occur, with rates of substance use disorders as high as 70% in people with schizophrenia. In a large European study of first-episode schizophrenia, already 31.1% of patients reported a comorbid substance use disorder, including 22.2% who used marijuana. Comorbid substance use is associated with poorer medication adherence, more hospitalizations, and overall worse functional outcomes, with the worst effects seen in heavy substance users.

Schizophrenia-Spectrum Case

A 21-year-old male college student was brought to the student health service by his resident advisor. The resident advisor noted that over the past several months, the student withdrew from fellow students and stopped participating in dormitory activities. His grades suffered, and he was caught smoking marijuana in his room. He recently began putting tape over the cameras in the computer lab and foil over the windows of his room. When asked about these behaviors, the student said that the Central Intelligence Agency (CIA) was tracking his movements through a vast network of computers. He spent several nights sleeping in the library or in a local 24-hour coffee shop to avoid detection. He believed that the CIA considered him to have special knowledge of operations within the government. The student believed that everyone knew about him because the CIA had put up a Web site about him. He said that he could hear agents and other people talking to him through the walls of his room, commenting on his behaviors, and telling him that he was stupid. His sleep was poor, and he was using marijuana to help sleep and to manage his anxiety.

Management and Outcome

Antipsychotic Medication

The mainstay of treatment for schizophrenia and other psychotic disorders is antipsychotic medication. Antipsychotics reduce psychotic symptoms and reduce relapse rates LEVEL 1.[1] All currently available antipsychotic medications antagonize dopamine D_2 receptors in the brain, which is thought to be their primary mechanism of action. Historically, antipsychotic medications have been categorized based on their potency at the D_2 receptor into high-potency and low-potency categories. Antipsychotics also affect other neurotransmitters including serotonergic, histaminergic, and adrenergic receptors. Effects on the various neurotransmitters determine therapeutic and adverse effects.

All antipsychotic drugs are capable of inducing neurologic side effects including abnormal involuntary movements known as *tardive dyskinesia* (TD), *akathisia* (restlessness), *dystonia*, and *pseudoparkinsonism* (tremor, rigidity, and bradykinesia) (Table 153.2). By definition, TD is associated with prolonged (at least 3 mo) exposure to an antipsychotic agent. Increased age, female gender, and duration of exposure are the greatest risk factors for TD. Newer (or second-generation) antipsychotics tend to have lower risk of TD, but risk varies according to individual drug characteristics as well as dose and duration of exposure. Drugs with lower potency at the D_2 receptor tend to be associated with more adverse metabolic side effects (weight gain, diabetes, dyslipidemia), whereas those with higher potency are more likely to cause neurologic side effects. Severe dystonias, especially those involving laryngeal or extraocular muscles, require emergency treatment with intramuscular diphenhydramine (50 mg) or benztropine (2 mg). Oral benztropine (1-4 mg daily) is effective for treatment of antipsychotic-induced tremors, and propranolol (30-90 mg daily) is often used for treatment of akathisia.

Metabolic side effects are closely associated with many antipsychotic treatments, in particular clozapine, olanzapine, quetiapine, and risperidone. The mechanism by which antipsychotics cause these effects is not conclusively known. Schizophrenia has long been associated, even before the introduction of antipsychotic medications, with increased rates of diabetes and obesity compared to the general population. Clozapine, olanzapine, and

TABLE 153.2 Selected Information on Commonly Used Antipsychotics[a]

Antipsychotic Medication	Typical Daily Dose Range for Schizophrenia (mg)	Metabolic Side Effects/Weight	Akathisia/ Pseudoparkinsonism	Prolactin Elevation	Sedation	Anticholinergic Side Effects	Orthostatic Hypotension

Abbreviations: +, low risk/mild effects; ++, medium risk/moderate effects; +++, high risk/severe effects; −, minimal risk.

[a]Data from Lawrence RE, Stroup TS, Lieberman JA. Schizophrenia spectrum disorders. In: Roberts LW, ed. *The American Psychiatric Publishing Textbook of Psychiatry*. 7th ed. Washington, DC: American Psychiatric Association; 2019:257-278; and Buchanan RW, Kreyenbuhl J, Kelly DL, et al. The 2009 schizophrenia PORT psychopharmacological treatment recommendations and summary statements. *Schizophr Bull*. 2010;36(1):71-93.

quetiapine are potent antihistaminergic agents and thus are associated with drowsiness and central histamine H_1 receptor activity, which may contribute to their risk of weight gain. Other theories regarding the metabolic effects focus on shared signaling pathways between insulin regulation and psychosis involving the kinase *AKT1* in the brain, pancreas, and liver. Peripheral response to antipsychotic drugs may feedback to the brain in a way that alters insulin secretion, which may have effects on weight. Although diabetes may often result from the central adiposity associated with antipsychotics, there are likely multiple pathways responsible for these metabolic effects because people may develop insulin resistance and diabetes in the absence of weight gain and vice versa.

A dangerous but rare side effect of antipsychotic drugs is neuroleptic malignant syndrome (NMS). NMS is characterized by tremors, muscle rigidity and myalgias, extreme fever, other autonomic instability, and altered mental status. The muscle rigidity ultimately leads to rhabdomyolysis, with increased creatine kinase and white blood cell counts. The resultant muscle breakdown products can lead to acute renal failure. Without rapid and intensive intervention, NMS can be fatal and is in nearly 10% of cases. Treatment of NMS focuses on stopping the antipsychotic immediately, cooling the hyperthermia rapidly, and protecting the kidneys from myoglobinemia through aggressive hydration.

Antipsychotics differ mainly in side effects, but some small to moderate differences in efficacy have also been detected. All three of the medicines with better efficacy that are available in the United States (clozapine, olanzapine, and risperidone) are associated with adverse metabolic effects. This finding leads to a clinical dilemma in which clinicians and patients must balance the opportunity for maximum symptom improvement with significant metabolic risk.

Clozapine has a special role because it is more efficacious than other antipsychotics in patients with treatment-resistant schizophrenia and has been shown to decrease suicidality and to cause the fewest abnormal involuntary movements. However, in addition to weight gain and significant metabolic side effects, clozapine is also associated with agranulocytosis and subsequent risk of death due to infection. Therefore, patients taking clozapine must be enrolled in a clozapine registry (www.clozapinerems.com) and monitored carefully for decreases in granulocyte counts. Other risks of clozapine include myocarditis and seizures. However, with close clinical monitoring, clozapine can be highly effective for many patients.

TABLE 153.3 Medical Conditions That Can Present With Psychosis

Delirium
Dementia/neurodegenerative disorders
Neoplasms
Seizures
Intoxications/medications
HIV/AIDS/other infections
Autoimmune/limbic encephalitis
Systemic lupus erythematosus
Neurovascular events
Leukodystrophies
Endocrine disorders
Mitochondrial disorders

Abbreviation: HIV, human immunodeficiency virus.

Nonpharmacologic Treatment

Nonpharmacologic treatments for schizophrenia that are supported by some evidence include repetitive transcranial magnetic stimulation for auditory hallucinations that do not respond to antipsychotic medications LEVEL 1.[1] Several psychosocial treatments are effective for specific problems associated with persistent psychotic illnesses. For example, multidisciplinary teams known as *Assertive Community Treatment* teams provide outreach and comprehensive care, which reduces rates of hospitalization LEVEL 1.[2] Supported employment programs are effective in helping people with schizophrenia obtain jobs LEVEL 1.[2]

OTHER CAUSES OF PSYCHOSIS

When a patient presents with psychosis for the first time, it is important to remember that psychotic symptoms are associated with numerous brain conditions, and the cause may not always be identifiable (**Table 153.3**). A thorough workup should be conducted to make sure that potentially reversible causes of psychosis are ruled out.

The workup for reversible causes of psychosis should start broadly and then focus more narrowly according to the specific presentation (**Table 153.4**). Laboratory tests are used to investigate possible metabolic or nutritional abnormalities, signs of infection/inflammation, and autoimmune processes. Neuroimaging may be indicated, particularly if there are focal neurologic

TABLE 153.4 Suggested Medical Workup for Psychosis[a]

In all patients
• Complete blood count
• Glucose, chemistries, liver function tests
• Thyroid-stimulating hormone
• Vitamin B_{12} and folate
• Urinalysis
• Urine drug screen
• HIV test
Secondary testing to be done as clinically indicated
• Brain imaging with CT or MRI
• Electroencephalogram
• Lumbar puncture
• Chest radiography
• Blood and urine cultures
• Arterial blood gases
• Serum cortisol levels
• Antinuclear antibodies (to test for autoimmune disorders such as systemic lupus erythematosus)
• Ceruloplasmin (to test for Wilson disease)
• Rapid plasma reagin (to test for syphilis)
• Toxin search/drug levels

Abbreviations: CT, computed tomography; HIV, human immunodeficiency virus; MRI, magnetic resonance imaging.

[a]Based on Freudenreich O, Schulz SC, Goff DC. Initial medical work-up of first-episode psychosis: a conceptual review. *Early Interv Psychiatry*. 2009;3(1):10-18.

deficits or an acute personality change. Lumbar puncture and electroencephalogram may also be part of a workup when associated symptoms suggest the possibility of infection.

Delirium is a common cause of psychosis and should be suspected in any patient with acute psychosis, particularly those who are older than typical first-episode psychosis patients. Although the definitive intervention for delirium is treatment of the underlying medical condition, there are important steps to take while the underlying cause is sought and treated. The first step is to ensure the patient's physical safety. Efforts to normalize the sleep-wake cycle should be a priority. Frequent reminders of location, time, and situation are helpful to reorient patients to their surroundings. Medications that cause or exacerbate delirium, including anticholinergic agents, should be avoided as much as possible. Benzodiazepines should also be avoided in nonalcoholic delirium. Antipsychotic medications can be useful in symptomatic treatment of delirium and associated psychosis. Antipsychotics have been shown to shorten the duration of delirium episodes with similar efficacy seen across multiple agents.

Psychosis frequently occurs in the setting of drug intoxication and withdrawal states. In severe alcohol and benzodiazepine withdrawal, patients may experience delirium tremens, which is fatal in approximately 1% of cases. This is characterized by autonomic instability, hallucinations, and agitation. Benzodiazepines (eg, lorazepam 2 mg every 2 h as needed) are the mainstay of treatment for significant alcohol withdrawal and delirium tremens LEVEL 1.[3] Many forms of drug intoxications can yield psychotic symptoms. Cannabis, particularly because it has become more potent in recent years, often causes a transient psychotic state characterized mostly by paranoia. Sympathomimetic drugs, such as amphetamine or methamphetamine, can cause paranoia and hallucinations with acute and chronic use. *N*-methyl-D-aspartate (NMDA) antagonists such as primary care provider and ketamine are also associated with auditory hallucinations, paranoia, and negative symptoms. These drugs, as well as amphetamines, are often used in animal models of schizophrenia because of the similarity in presentation to schizophrenia. Tactile hallucinations are often seen with amphetamines and cocaine.

Psychosis is also common in major neurocognitive disorders such as dementias. Patients with dementia often report paranoid delusions or feelings that people are stealing from them. In dementia with Lewy bodies (DLB), many patients report delusions and visual hallucinations (including "lilliputian hallucinations" of little people/animals) and develop pseudoparkinsonism even with low doses of antipsychotics. Antipsychotics can be helpful in treating these psychotic symptoms and can help reduce dementia-related agitation but should be used with caution and in low dosages. In many circumstances, cholinesterase inhibitors are effective and should be considered first in DLB. If using antipsychotics in treating patients with DLB, quetiapine, at low doses (eg, 25-50 mg daily), is a good first choice. Clozapine (eg, 25-50 mg daily) is a second choice if quetiapine is not effective; it has substantial anticholinergic effects and requires close monitoring of white blood cell counts because of a risk of agranulocytosis. Dementia is not a U.S. Food and Drug Administration–approved indication for antipsychotics, and all antipsychotics carry a black box warning for this use because of an increased risk of mortality for elderly dementia patients. The possible benefits of antipsychotics in reducing psychosis or agitation must be weighed against the small but significant risk of increased mortality as well as the other adverse effects of antipsychotics. Importantly, if an antipsychotic is used for a patient with dementia, it should be discontinued unless there are clear benefits.

Dementia With Lewy Bodies Case

A 70-year-old woman who lives alone and has demonstrated increasing problems with self-care was brought for evaluation by her two grown sons, she reports she has become frightened by strange people coming in to her yard; the sons believe that she was "seeing things." Upon questioning, it became clear that the strangers, because of their reported tiny size, were in fact visual hallucinations. Her Mini-Mental State Examination score was 24 of 30. Although further evaluation was pending, she began symptomatic treatment with low-dose risperidone. She experienced severe "stiffness." On exam, she was rigid and had minimal facial expression. In retrospect, it became clear that she had experienced significant bradykinesia over several months. When risperidone was switched to quetiapine her rigidity and bradykinesia improved but persisted.

Because brain tumors can have many psychiatric manifestations, including psychosis, the workup for new-onset psychotic symptoms should include neuroimaging. The presence of other focal neurologic findings should raise the index of suspicion for psychosis secondary to a brain lesion. Peripheral tumors including small cell lung cancer (and resultant paraneoplastic syndrome), steroid-producing hormones such as adrenal tumors (Cushing disease), and pheochromocytoma may also cause psychosis. Another rare cause of psychosis is autoantibodies to the NMDA receptor. These antibodies, most often seen in young women, often derive from ovarian teratomas or other tumors; surgical removal of the tumors may resolve the symptoms. Immunotherapy (eg, steroids, intravenous immunoglobulins, and plasmapheresis) can also be used to treat the psychosis and associated symptoms with good effect.

Seizures may also cause psychotic symptoms, and the presence of other seizure sequelae, such as auras or postictal periods, should prompt testing in that domain including electroencephalogram. Psychosis may occur intraictally or postictally. Temporal lobe epilepsy is classically associated with psychotic symptoms including déjà vu (a sense of reexperiencing something that is novel), fear without identifiable cause, or olfactory hallucinations. Treatment of epileptic-related psychosis can be complicated because antipsychotic medications can lower the seizure threshold. However, this effect is generally not clinically significant except in the case of clozapine (eg, at doses ≥600 mg daily or when blood levels rise rapidly). Some antiepileptic drugs including levetiracetam, vigabatrin, and topiramate can worsen psychosis. In addition, carbamazepine induces antipsychotic drug metabolism and may lead to decreased blood levels, resulting in the emergence of psychotic symptoms. On the other hand, valproic acid (eg, 500-1,500 mg daily) is commonly used off-label as adjunctive agent to potentiate the initial efficacy of antipsychotic drugs in the treatment of schizophrenia, although the efficacy of this strategy is uncertain. Ultimately, if antipsychotics are indicated in someone with a seizure disorder, then the choice of drug depends largely on tolerance for side effects and drug-drug interactions.

A number of infections are known to cause psychosis. Infections that yield brain lesions, such as neurocysticercosis or other fungal infections, seen as ring-enhancing lesions on magnetic resonance imaging, can cause both seizure activity and associated psychosis. Up to 15% of human immunodeficiency virus (HIV) patients may experience psychotic symptoms generally through opportunistic infections, HIV-associated neoplasms, or HIV-associated delirium/dementia. More commonly, HIV is associated with psychotic symptoms, both through progression of the illness or through drug interactions with antiretroviral

therapy or from highly active antiretroviral therapy medications themselves. Other infections sometimes associated with psychosis include Lyme disease, herpes, and neurosyphilis. Herpes encephalitis, the most common sporadic viral encephalitis in the United States, requires immediate attention because there is a high risk of mortality if not treated promptly. Acyclovir (30 mg/kg/d) should be started while waiting for the results of lumbar puncture and imaging studies.

Many medications are associated with psychosis. Steroids are most commonly implicated in causing psychotic symptoms and can also cause other significant emotional side effects including depression and anxiety. Treatment of Parkinson disease is often complicated by psychosis when using prodopaminergic agents. Low doses of quetiapine (25-50 mg daily) or clozapine (25-50 mg daily), which have a relatively low risk of pseudoparkinsonism, are recommended for treating psychotic symptoms in patients with Parkinson disease. Psychoactive medications including sympathomimetic agents, opioids, and benzodiazepines can cause psychosis, particularly in high dosages. Psychosis has also been reported to be associated with antibiotics, antimalarials (particularly mefloquine), antituberculous drugs, and muscle relaxants.

Delirium With Psychosis Case

A 73-year-old man is admitted to orthopedic surgery for surgical repair of his left hip. On postoperative day 2, nurses report that he is agitated and complaining that he sees a "crippled equestrian" near the air conditioning vent. Nurses also report that he was awake much of the night and sleeping during the day. He was given lorazepam last night to help him sleep, but the report from nursing staff is that it made him agitated, and he needed to be placed on 1:1 observation because he did not sleep and tried to get out of bed unsafely. He's been picking at his bed sheets and nearly pulled out his intravenous line. When you see him at the bedside, he says that the year is 1968, and he is at a racetrack. His vital signs show a low-grade fever and tachycardia, and his complete blood count shows a mildly elevated white count.

CONCLUSION

Psychosis presents in many psychiatric and other medical conditions and is generally a sign of a severe underlying problem. Not all cases of psychosis are due to a primary psychotic disorder such as schizophrenia, and many represent urgent medical problems. This is particularly important in older patients and in cases that do not otherwise fit the typical pattern of schizophrenia onset. A broad differential should be considered to identify reversible and potentially progressive causes of psychosis. Prompt, appropriate treatment should lead to improved outcomes.

Mood Disorders 154

Andrés Barrera, Licínia Ganança, Alejandro S. Cazzulino, and Maria A. Oquendo

KEY POINTS

1. Major depressive episodes can occur in both bipolar and unipolar syndromes with a minimum duration of 2 weeks.
2. Major depressive disorder has a 12-month prevalence of 13.4% for women and 7.2% for men.
3. Major depressive disorder somatic therapies include antidepressants, transcranial magnetic stimulation, and electroconvulsive therapy.
4. Bipolar disorders have a lifetime prevalence of 0.3% to 1.5% and a female-to-male ratio of 1:1.
5. Bipolar disorder pharmacotherapy includes lithium, valproate, lamotrigine, carbamazepine, dopamine blockers, and electroconvulsive therapy.

INTRODUCTION

Mood disorders are defined by the presence of a distinct period of persistently altered mood, specifically, depressed, manic, or hypomanic states. These states may signal the presence of depressive or bipolar disorders depending on the presenting symptoms and the longitudinal course of the illness. It is fundamental to differentiate between major depressive disorder (MDD) and bipolar disorder because they have different clinical presentations, prognoses, etiologies, genetic factors, and importantly treatments. Moreover, treating bipolar disorder with antidepressants alone may precipitate hypomanic or manic episodes.

Comorbidity between mood and neurologic disorders occurs frequently. Mood, especially depressive, symptoms may be part of or precede the clinical presentation of some neurologic disorders (eg, Huntington disease [HD]). They may also increase the risk for cerebrovascular disorders, and possibly some dementias, and therefore have a considerable impact in the prognosis and quality of life of primary neurologic disorders.

EPIDEMIOLOGY

It is estimated that 300 million people worldwide are affected by depression. Major depression is one of the leading causes of disability in the United States and worldwide; it ranked 11th in terms of disability-adjusted life years in a study of 291 diseases and injuries conducted in 21 regions. Moreover, according to the National Mental Health Association, depression affects 1 in every 33 children and 1 in every 10 adolescents (13.3%.) In any given year, about 21 million people in the United States will suffer from major depression (https://www.nimh.nih.gov/health/statistics/major-depression.shtml).

The incidence of depression is nearly twice as high in women as it is in men, and suicide attempts are more numerous in women. However, death from suicide is far more common in men. Additionally, postpartum depression occurs after as many as 10% of all deliveries. The 12-month prevalence of depression in the U.S. population is estimated to be around 8.7% for women and 5.3% for men.

Bipolar disorder has a lifetime risk of 0.3% to 1.5%, with equal prevalence among men and women. It is estimated that around 22.5% of depressed patients may in fact be bipolar but have yet to be diagnosed.

PATHOBIOLOGY

Mood disorders result from the interaction between biologic (genetic) and environment factors. Genetic factors are thought to be relevant due to the high heritability of mood disorders, estimated at about 30% to 40%. The data from twin studies indicates that environmental factors also play an important role in the expression of mood disorders. Nonetheless, the risk of becoming ill increases two- to threefold for first-degree family members of patients with mood disorders. It is for this reason that interest in epigenetic studies in mood disorder—which concurrently take into account both explanatory factors—is increasing. Of note, despite early suggestions that bipolar disorder is more heritable than depressive disorders, the evidence that genetic vulnerability or heritability of mood disorders differs between bipolar and unipolar conditions is mixed and far from definitive.

Pathophysiology of Major Depressive Disorder

With the growing availability of functional and structural brain magnetic resonance imaging and of treatments like transcranial magnetic stimulation (TMS), which targets specific brain circuits, there is a better understanding of the significant changes in the structure and function of the brain in unipolar depression. Findings indicate that the core pathologic dysfunction in unipolar depression appears to be in the prefrontal/limbic network. At the same time, this network influences and is highly influenced and modulated by at least three other systems: hypothalamic-pituitary-adrenal (HPA) axis, the basal ganglia network, and the mesolimbic network.

Prefrontal/limbic dysregulation is characterized by a decrease in activity and/or volume in several dorsal structures: the dorsolateral prefrontal cortex (PFC), dorsomedial PFC, dorsal anterior cingulate cortex (ACC), and rostral ACC. In contrast, there is increased activity in ventral structures, the amygdala, the subgenual ACC, the ventrolateral PFC, and orbital PFC. The hippocampus plays a special role, although medial and deep in

FIGURE 154.1 Neurocircuitry of major depressive disorder.

the temporal lobe, showing marked hypoactivity and significant volume loss. Simply stated, the prefrontal network, which under normal circumstances controls and regulates the limbic system and thus mood, is overpowered by the limbic system. In a depressed state, the limbic network "controls" the prefrontal network, yielding a state in which unregulated mood can take over.

The HPA axis—part of the stress system—is central in depressive disorders and may provide a "gateway" for a new mood episode. Stress has been implicated in the pathophysiology of depression not only as mediated through glutamatergic changes in response to stress but also as exemplified by prominent changes to the neuroendocrine system. Under normal conditions, stress prompts the HPA axis to secrete serum cortisol. In mood disorders, the HPA axis may become unresponsive to the normal negative feedback loop, leading to a failure to restore cortisol to normal levels once the stressor is removed. These changes may be accompanied by the loss of normal diurnal variation in cortisol levels. Whether these changes are linked to negative early life experiences, leading to enduring changes in the HPA axis thereby increasing the probability of developing a mood disorder later in life, is not known. Chronic increases in cortisol levels have been implicated in the activation of the amygdala and possibly the subgenual ACC as well as in a decrease in activity and volume of the hippocampus and rostral anterior cingulated cortex.

The relation between the basal ganglia and the prefrontal/limbic network is highly complex. There are at least four circuits between the basal ganglia and the prefrontal/limbic network, some of which are implicated in the control of goal directed behavior (rewards and punishments) and rumination, two activities central to the manifestation of mood disorders. Finally, the mesolimbic network, specially the dysregulation of the dopaminergic projections from the ventral tegmental area to the nucleus accumbens and PFC are keys to understanding anhedonia, a core symptom of depression. The decrease in dopaminergic tone mediates the lack of motivation, interest, and incapacity for joy in depression (Fig. 154.1).

The neurotransmitter systems involved in the dysfunction of these circuits in MDD include the serotonergic, glutamatergic, noradrenergic, and dopaminergic systems. The serotonergic system plays a key role in depression, with studies demonstrating an overall decrease in serotonin (5-HT) function. Brain imaging studies demonstrate increased 5-HT_{1A} receptor binding, with 5-HT_{1A} upregulated in response to low serotonergic tone and fewer brain 5-HT reuptake sites. Tryptophan (5-HT precursor) depletion has been shown to produce rapid depressive relapses in patients with a history of depression, but no change in subjects with no personal or familial history of mood disorders. This suggests that low levels of 5-HT in the brain are not sufficient to cause depression but may act in concert with other factors in vulnerable individuals to cause symptoms. Indeed, many antidepressants exert their action through modulation of 5-HT transmission.

Dopamine also has a fundamental role in mood disorder. It is involved in motivation, incentivized behavior, and reward and therefore is key to understanding anhedonia—perhaps the most characteristic symptom of depression. Low cerebrospinal fluid levels of the dopamine metabolite, homovanillic acid, have been documented in depressed patients, and exposure to dopamine-depleting drugs such as reserpine is known to precipitate depression. On the other hand, some antidepressants like bupropion and sertraline and stimulants like amphetamines and methylphenidate increase dopaminergic tone in the ventral tegmental area–nucleus accumbens circuit improving motivation, activity, attention, and energy in depressed patients.

Changes in other neurotransmitters such as norepinephrine and glutamate have also been identified. Norepinephrine is linked to the pathophysiology of severe depression; studies have shown decreased norepinephrine turnover, increased metabolites of norepinephrine, and induced depressive episodes with

norepinephrine depletion by reserpine. Glutamate, the main excitatory neurotransmitter appears to be increased in major limbic and cortical systems, possibly in response to stress, and may exert pathogenic effects either by limiting neurogenesis or dendritic remodeling directly, enhancing apoptosis or may act in concert with other factors having effects on neuroplasticity.

Other neuropathologic aspects of depressive disorders have received significant attention. For example, depression is associated with neuroinflammatory processes, comporting with the observation that depressive symptoms (fatigue, anhedonia, anorexia, etc) could be viewed as "sickness behaviors." Indeed, changes in inflammatory markers, such as increased interleukin 6 and tumor necrosis factor α levels have been consistently found in patients with depression. Furthermore, administration of therapeutic cytokines has been shown to cause significant depressive symptoms in 50% of exposed individuals, providing further evidence for the role of neuroinflammation.

As noted earlier, neuroplastic changes in the hippocampus have been linked to depression. Chronic stress is associated with decreased hippocampal neurogenesis, a phenomenon observed in animal models of depression and postmortem tissue. Treatments with antidepressants seem to reverse these hippocampal deficits in neurogenesis. Both stress and antidepressants have been shown to affect levels of brain-derived neurotrophic factor (BDNF), which is normally highly expressed in hippocampus and PFC and plays a major role in neuronal growth, survival, and maturation. BDNF also seems to have antidepressant-like actions and can induce molecular transcription in several key pathways.

Some psychosocial models focus on loss as the cause of depression in vulnerable, or less resilient, individuals. Exogenous factors may include social rejection or loss (interpersonal, financial, or health-related). Certainly, loss of income, job, social status, or the failure to achieve a life goal may produce profound mourning. Regardless, clinical symptoms that develop in response to these stressors are ultimately mediated through brain circuitry and neurochemistry.

Pathophysiology of Bipolar Disorder

The pathophysiology of bipolar disorder is still being clarified; it needs to address not only very different states: depressive and manic or hypomanic episodes but also a dynamic dysfunction between them: the change across episodes, from the extreme energy and expansive mood of mania to the lack of energy and depressed mood of depressive episodes. As in MDD, the core pathologic dysfunction in bipolar disorder is in the mood regulation in the prefrontal/limbic network; specially decreased control of the ventral PFC over the amygdala and the nucleus accumbens. Functional neuroimaging has shown hyperactive amygdala as well as ventral striatum and hypoactive ventral PFC. Structural evidence from brain imaging studies shows a reduction of volume, presumably neurons and glial cells, in areas such as the PFC, amygdala, and striatal regions, as well as white matter hyperintensities. As is the case in major depression, positron emission tomography studies suggest serotonergic abnormalities including fewer 5-HT transporters and more 5-HT_{1A} receptors. Other relevant neurotransmitters include dopamine and glutamate. For instance, drugs that increase dopamine release, such as amphetamines, can induce manic-like symptoms. Similarly, decreased dopamine reuptake and reductions in dopamine transporter availability are linked to bipolar disorder. In addition, increased cortical glutamate levels and vesicular glutamate transporter gene expression are also implicated in the neurobiology of bipolar disorder.

As with depression, bipolar disorder can be viewed as a disorder related to synaptic plasticity involving dysfunction of neuroprotective pathways and impaired neuronal resilience. Multiple pathways related to plasticity are implicated, including impaired regulation of calcium signaling cascades, associated with oxidative stress, and mitochondrial and endoplasmic reticulum stress response dysfunction.

Several intracellular molecular pathways affected by lithium and pertinent to neuroplasticity have been investigated as potential pathophysiologic contributors. The phosphoinositol pathway, involved in protein kinase C activation, regulates expression of several genes including BDNF. In fact, altered levels of BDNF are posited to contribute to the polarity switch process. Another lithium target, glycogen synthase kinase 3, is a key component of Wnt signaling and has effects on neurotransmission, neuroplasticity, neuronal growth, and metabolism.

As we describe in this chapter, bipolar disorder is a different illness than MDD, with distinct treatment and prognosis. Therefore, to clarify differences in pathologic processes is essential not only to define etiology but also to identify biomarkers that might help in the differential diagnosis. Recent functional imaging studies show differences in the connectivity within the insula and the parietal lobe differentiating bipolar depressed patient from unipolar depressed patient and healthy subjects.

CLINICAL MANIFESTATIONS

Depressive Disorders

A depressive episode is distinct from the normal emotional feelings of sadness or loss or a passing state of these emotions. Functional impairment and significant distress are key criteria, and indeed, depression encompasses dysfunction in affective, cognitive, behavioral, and psychomotor domains.

In order to make the diagnosis, at least one of two gateway symptoms must be present for a minimum of 2 weeks: depressed mood and/or substantial decrease in interest or pleasure. Interestingly, depressed mood can manifest in a variety of ways, and patients may report feeling down, sad, depressed, anxious, angry, or irritable. Of note, males may be more likely to present with irritability or anger, sometimes making the diagnosis more challenging to identify. Women more often present with "classic" sadness or depression. Anhedonia, or inability to feel pleasure, manifests as a reduction or loss of interest in things, people, or activities. As "gateway symptoms," the diagnosis of depression cannot be made in the absence of at least one of them.

Cognitively, patients may experience difficulty concentrating or making decisions, a decrease in productivity, forgetfulness, and slowed thoughts. In addition, patients often report distorted thoughts that are negative and pessimistic, including feelings of worthlessness, loss of self-esteem, and unreasonable self-blame or guilt. The future is regarded with a sense of dread and hopelessness. Moreover, negative memories from the past may be preferentially recalled. At times, such cognitive distortions may be of delusional intensity. For example, patients may become convinced they are gravely ill or impoverished and unable to process or "believe" results from medical tests or bank reports. Other delusions typical of depression with psychotic features

focus on pessimism or deserved punishment. Auditory hallucinations are usually simple and mood congruent, for example, patients may hear a single word or short phrases with guilt, punishment, illness, death, or worthlessness content.

The behavioral symptoms of depression include changes in appetite and weight and disruptions of sleep patterns. Sleep disturbances include difficulty falling asleep (early insomnia), waking up in the middle of the night (middle insomnia), and waking up earlier than usual (terminal insomnia). Middle and terminal insomnias are more specific to depression than early insomnia, which is more common in the absence of a mood disorder. However, some patients experience hypersomnia rather than insomnia. Similarly, patients often report poor appetite and weight loss, although increased appetite and weight are sometimes observed, too. Other behavioral symptoms include loss of libido.

Psychomotor activity is usually diminished in depression and low energy and physical fatigue are often present. Patients may experience difficulty completing day-to-day activities and self-care or find that these activities require greater effort. In extreme cases, patients may become virtually immobile and mute, and this condition combined with loss of appetite and overall self-neglect can result in a medical emergency due to dehydration or poor nutrition. In contrast, some patients exhibit psychomotor agitation, which is often accompanied by intense anxiety. Agitation can often not only be seen in depressed patients but may also result from the side effects of antidepressant medications.

Perhaps, the most worrisome symptom of depression is suicidal thinking or behavior. Suicidal ideation may range from passing thoughts that life is not worth living to well-defined plans with intent to kill oneself. About 15% of patients with depression acknowledge a suicide attempt at some point in their lives and between 2% and 12% of patients with depression die by suicide. This is another way in which depression can lead to morbidity and mortality.

On examination, depressed patients characteristically exhibit a dejected posture, with bent shoulders, frowning, and a downcast gaze. Gestural movements and facial expressions are reduced, and grooming may be neglected. Patients usually take more time to start answering questions and speak slowly and softly.

Bipolar Disorders

The distinguishing feature of bipolar disorder is the presence of a manic episode that lasts at least 1 week or longer or a hypomanic episode that lasts at least 4 days or longer. Beside duration, hypomania is characterized by the same symptoms seen in mania, but of less severity. Generally, impairment in hypomania is less pronounced than in mania. This distinction between mania and hypomania allows the classification between bipolar I (manic episodes) and bipolar II (hypomanic episodes). Bipolar disorder also is characterized for dysfunctions in affective, cognitive, psychomotor, and behavioral domains. There are other subtypes of bipolar disorder; cyclothymic disorders (hypomanic and depressive symptoms not enough to meet full criteria), substance/medications induced bipolar disorder, and bipolar disorder related to another medical condition.

As described before, mania, lasting a minimum of 1 week, is characterized by abnormally elevated or euphoric feelings. As with depression, there can be significant irritability and anger, especially when the patient is frustrated, but patients often appear exaggeratedly cheerful and happy. By definition, mania causes severe impairment.

Cognitive abnormalities include rapid or even racing thoughts, which may translate into rapid, pressured speech that can, as the severity of mania progresses, become increasingly disorganized. As thoughts become disorganized, speech can exhibit flight of ideas or loosening of associations. In addition, patients are easily distracted and have difficulty focusing on tasks that require concentration. Patients also frequently exhibit impaired judgment and engage in activities they would normally eschew if well. Patients may go on spending sprees, engage in promiscuous sexual behaviors, or make risky business decisions. Cognitive distortions in mania often include inflated self-esteem and grandiose ideas such as a sense of being special, capable of anything, or possessing special powers. As in depression, the cognitive distortions can cross the line into delusional or psychotic thinking. Grandiose delusions are a common psychotic feature in mania.

Behaviorally, manic patients are usually overactive with increased energy levels and engage in multiple activities. Typically, the number of hours of sleep is reduced, without the sensation of fatigue or sleepiness. In fact, insomnia is often the first recognizable symptom of a manic episode. Appetite is usually reduced and combined with increased activity can lead to significant weight loss. Manic patients classically dress with bright colors, use excess make up, or wear extravagant clothing. Movements are exaggerated or theatrical, and patients may express excessive familiarity toward strangers.

From a psychomotor vantage, manic patients frequently have increased psychomotor activity. They may both engage in goal-oriented activities at an accelerated pace or be overactive in a general way, with pacing or fidgeting.

Interviewing can be very difficult because manic psychopathology tends to block communication. It is usually counterproductive for the physician to spend time arguing with or countering the illogical thinking of the patient. Insight is absent in virtually all cases and, therefore, patients typically object to treatment.

Hypomania has a similar clinical presentation but may be briefer, cause less functional impairment, and has no psychotic symptoms.

Although the presence of manic or hypomanic episodes differentiates bipolar from depressive disorders, depression is prominent in bipolar disorder. In fact, over the course of the disorder, most bipolar patients spend significantly more time depressed than manic or hypomanic. Bipolar depression usually has an earlier onset, greater risk of suicidal behavior, likely linked to the greater time spent depressed, and more episodes of illness.

Seasonal Affective Disorder

Seasonal affective disorder is characterized by episodes that regularly occur in a specific season. The most notorious is MDD occurring during winter, also known as *winter depression*. It typically starts in the fall and extends until the spring. In addition to other symptoms of depression, specially anhedonia, low energy and inactivity, seasonal affective disorder is characterized by increased sleep, increased appetite, and weight gain. As many as 15% of patients with MDD have a seasonal presentation. The pathogenesis, although not known, has been associated with disturbance in the circadian rhythms in the context of decreased daylight during the winter.

DIAGNOSIS

There is no pathognomonic sign or symptom and, as of yet, no biologic or neuroimaging markers that can establish the diagnosis of a mood disorder. Therefore, mood disorder diagnoses are established according to their clinical features. Each category has specific criteria, which are defined by consensus and described in manuals such as the *Diagnostic and Statistical Manual of Mental Disorders* (fifth edition, *DSM-5*). It is likely that these diagnoses will ultimately be understood as a grouping of multiple distinct disorders and more specific entities within the current disorders will be defined using genetics, epigenetics, brain imaging, and other methods.

MDD is diagnosed by the presence of at least one major depressive episode. Episodes can occur a single time but, more often, they are recurrent. Additionally, episodes can occur with mixed symptoms of hypomania but without meeting the full criteria for hypomania (or mania). If full criteria for manic or hypomanic episode and full criteria for major depressive episode are present at the same time, the diagnosis is bipolar disorder with mixed features.

DSM-5 criteria for MDD requires a least five of the following symptoms: (1) depressed mood, (2) anhedonia (loss of interest, motivation, or pleasure), (3) weight loss or gain, (4) insomnia or hypersomnia, (5) psychomotor agitation or retardation, (6) loss of energy, (7) low self-esteem or inappropriate guilt, (8) decreased capacity to think or concentrate or indecisiveness, (9) death or suicidal ideation or behavior. The duration of the episode needs to be at least 2 weeks. Recall that depressed mood and anhedonia are gateway symptoms and at least one of them must be present to make the diagnosis of major depression.

Persistent depressive disorder is a form of depression that has less than five symptoms, as required in MDD, but lasting for at least 2 years, with little or no remission during that time. Typical symptoms include low mood, lack of energy and interest, low self-esteem, and irritability. Chronic forms of depressive disorders are associated with poorer response to treatment, slower rate of improvement over time, younger age of onset, longer episodes, greater disease burden, higher rates of medical and psychiatric comorbidity, and higher rates of suicidal ideation.

Mood and associated physical symptoms may occur in relation to the menstrual cycle. **Premenstrual dysphoric disorder** is diagnosed if symptoms are present during the last week of the luteal phase, remit within a few days of the follicular phase, and are absent in the week following menses. A prospectively documented cyclical pattern over at least 2 consecutive months must be present to confirm the diagnosis.

Mood disorders in children and adolescents bring specific diagnostic challenges. Behavioral problems are common and include withdrawal, sullenness, truancy, poor grades, and tantrums. Children and adolescents showing persistent irritability, which manifests as frequent temper outbursts and angry, irritable mood in between outbursts, may be eligible for the diagnosis of **disruptive mood dysregulation disorder**. To meet the criteria, the temper outburst need to be frequent, three or more per week, and the symptoms must be present for at least 1 year.

The presence of at least one manic episode is required to diagnose a **bipolar I disorder**. In contrast, a **bipolar II disorder** diagnosis requires a history of both depressive and hypomanic episodes. Recurrence of episodes, interspersed with periods of normal mood (euthymia), is the norm, although single episodes are possible. In some cases, patients never fully recover and continue on a chronic course.

TABLE 154.1 Neurologic Disorders Commonly Associated With Mood Symptoms

Depressive Symptoms	Manic Symptoms
• Stroke (depression as both risk factor and sequelae) • Parkinson disease • Huntington disease • Essential tremor • Multiple sclerosis • Epilepsy • Dementia	• Focal strokes in right basotemporal and inferofrontal region • Stroke/tumor in perihypothalamic region • Huntington disease • Multiple sclerosis • Head trauma • Neurosyphilis • Creutzfeldt-Jakob disease • Frontotemporal dementia

Patients with **cyclothymia** alternate between mild, short-lived depressions and hypomania. The cycles may be continuous and last for several weeks to several months. Rarely do these patients complain specifically about the highs they experience. More commonly, patients will complain only of being depressed at times, not realizing that they have been hypomanic at other times. Cyclothymia is sometimes a precursor to the more classic form of bipolar disorder.

Substance/medication-induced bipolar or depressive disorders can occur when mood episodes develop during or soon after substance intoxication or withdrawal or alternatively after exposure to a medication. Note that in cases where mania or hypomania ensues after treatment with an antidepressant, the diagnosis of bipolar disorder is warranted if the manic/hypomanic symptoms do not remit on withdrawal of the antidepressant (considering the time needed for metabolic elimination of the compound). Similarly, **bipolar or depressive disorders due to another medical condition** occur when there is evidence from the history, medical examination, or laboratory findings that the mood episode is a direct pathophysiologic consequence of another medical condition. See **Table 154.1** for a list of common neurologic disorders associated with mood symptoms.

When patients present with the characteristic symptoms of a depressive or bipolar disorder, but do not meet full criteria, a diagnosis of **other specified bipolar or depressive disorders** can be established if the condition causes clinically significant distress or impairment (**Fig. 154.2**).

Differential Diagnosis

Sadness is a normal reaction to life adversity and is characterized by an adequate response in proportion to the provoking stimulus, relatively brief duration, and lack of a major impact on psychosocial functioning. In normal bereavement and adjustment disorders, there is typically a reduction in depressive symptoms after the removal of provoking stressors.

Some medical conditions cause prominent mood symptoms. In addition to the history and physical examination, laboratory testing should include hepatic and thyroid function, studies of electrolytes, calcium, blood urea nitrogen, creatinine, a complete blood count, urinalysis, and a urine drug screen.

Differential Diagnosis With Neurologic Disorders

Twenty-five percent to 40% of patients with neurologic conditions, including Parkinson disease (PD) and HD, as well as Alzheimer disease, develop a marked depressive syndrome at

FIGURE 154.2 Algorithm for major depressive disorder (MDD) diagnosis.

some point over the course of the illness. Mood symptoms may precede neurologic manifestations in the cases of PD, HD, and essential tremor (ET). Critically, PD shares some symptoms with major depression, such as bradykinesia, decreased or even expressionless faces, bradyphrenia, stooped posture, loss of interest and concentration, and reduced libido. Comorbidity between the two disorders is highly prevalent, around 40%. Bromocriptine treatment is also associated with depressive symptoms. Features that facilitate the diagnosis of depression in these patients include the presence of a pervasive low mood (sometimes with diurnal variation), early morning awakening, pessimism (not proportional to the level of neurologic disability), and suicidal ideation. Of note, some psychiatric drugs directly affect dopaminergic transmission, such as first- and second-generation antipsychotics, and can cause or worsen parkinsonian symptoms or cause tardive dyskinesias.

Depressive symptoms can occur in patients with ET with prevalences as high as 49%. Not only do these symptoms result from the functional impairment associated with a disabling tremor but also may be a part of the pathophysiologic process and in some cases precede the onset of motor symptoms. A recent study revealed lower scores on items such as "reported sadness," "inability to feel," and "pessimistic thoughts" in depressed patients with ET. Euphoria can also be seen in neuropathologic states. Frontal lobe lesions can manifest with euphoria, often in the form of silliness and lack of foresight. Extreme social disinhibition, in the absence of other features of mania, strongly suggests frontal lobe pathology.

Patients suffering from dementia may present with manic-like agitation or depression. Cognitive and behavioral changes mimicking depression, such as apathy and loss of concentration, are more common than those that mimic mania, such as restlessness and combativeness. The medical evaluation is most important in elderly patients because they are at the greatest risk for having another illness comorbid with depression. They may also have a different medical condition presenting as depression. Although "pseudodementia" may be a sign of depression in the elderly, this assumption should be regarded as a diagnosis of exclusion. The appearance of a late-life affective disorder, especially in patients with no family history of such a condition, suggests a medical etiology.

Psychiatric symptoms, such as irritability, impulsivity, anxiety, and depressed mood, are almost ubiquitous in HD, which may initially present as a depressive illness. Depression may predate the neurologic diagnosis by 4 to 10 years. Apathy is a symptom that typically worsens as the disease progresses and may be related to the disorder itself. Suicide and suicide attempts are common. Manic symptoms can occur but are not as common. Family history is indicative of HD, and the definitive diagnosis is made through genetic testing.

Mood disorders are very common in epilepsy, 55% of individuals with epilepsy report depression, and they tend to have a pleomorphic presentation, sometimes not meeting full *DSM-5* criteria. Depressed mood, irritability, and anxiety are common. Mood disorders are classified according to their temporal relation to the occurrence of seizures as ictal (during the seizure), peri-ictal (preceding or following the seizure), or interictal (independently of the seizure).

In some situations, as in the so-called masked depression, patients fail to report feeling sad or depressed and can present with pain, fatigue, and other vague medical complaints. The presence of at least five of the necessary symptoms establishes the correct

diagnosis. The differential diagnosis is especially important in neurology because these patients often complain of headaches or backaches that are not amenable to conventional treatments.

Sleep apnea can cause fatigue, diminished concentration, and other symptoms similar to those of depression. A polysomnographic study may be warranted, especially in obese patients presenting with depressive symptoms.

Differential Diagnosis With Other Psychiatric Disorders

The distinction between mood disorders and other psychiatric disorders can be difficult and further complicated by the fact that comorbidity is very common. The negative symptoms of schizophrenia, such as apathy, anhedonia, decreased motor activity, social withdrawal, and cognitive decline, can resemble depression. On the other hand, patients with schizophrenia can present with grandiose delusions and florid agitation similar to mania. In mood disorders, delusional themes tend to be congruent with the main presenting mood. A history of periodic psychotic illnesses with a return to proper functioning between episodes is more suggestive of an affective disorder, whereas a history of chronic or deteriorating functioning is more suggestive of schizophrenia. A diagnosis based on a longitudinal evaluation is the most reliable. In the case of schizoaffective disorder, in which psychotic and mood symptoms coexist, the persistence of psychotic symptoms after resolution of mood symptoms validates the diagnosis.

Comorbidity with substance abuse disorders is prominent. In community samples, over 50% of individuals with mood disorders meet criteria for alcohol and/or substance abuse disorders. Patients may view substance abuse as a form of "self-medication," but often, symptoms are in fact caused or exacerbated by the substance. Such changes may be limited to the period of intoxication or occur after intoxication. If intoxication occurs frequently, it may produce diagnostic uncertainty, and prolonged abstinence may be necessary to make an accurate diagnosis. Patients with mood disorders who abuse both alcohol and drugs are more difficult to treat and have a higher rate of suicide attempts and suicide. Alcohol is often used in suicide attempts and may be the factor that triggers impulsive, self-destructive behavior or that intensifies the effects of an overdose.

Depressed patients often have severe anxiety and sometimes experience panic attacks as part of their illness. Predominance of either anxiety or depressive symptoms usually helps to establish the correct diagnosis. Nevertheless, there is a high rate of comorbidity with depression and all forms of anxiety disorders.

In the case of personality disorders, especially borderline personality disorder, the differential diagnosis is made if characteristic personality features, such as feelings of emptiness, extreme rejection sensitivity, and frantic efforts to avoid perceived abandonment, exist outside mood episodes. Borderline personality disorder is often comorbid with mood disorders.

TREATMENT

Treatment of Depressive Disorders

Depression can be treated with either pharmacotherapy or manualized therapies such as cognitive behavioral therapy or interpersonal therapy LEVEL 1.[1] More severe depression may require both medication and psychotherapy. Hospitalization may be necessary, especially for actively suicidal patients or for those whose personal care is so impaired that around the clock nursing is essential.

Antidepressant medications are classified by molecular structure or by effects on neurotransmitters.

There are five main groups: selective serotonin reuptake inhibitors (SSRIs) (fluoxetine, escitalopram, etc), serotonin norepinephrine reuptake inhibitors (venlafaxine, duloxetine, etc), tricyclic antidepressants (TCAs) (imipramine, nortriptyline, etc), and monoamine oxidase inhibitors (MAOIs) (phenelzine, tranylcypromine), and atypical antidepressants (mirtazapine, bupropion, vortioxetine, etc) LEVEL 1.[2-7] Any of these drugs are a good choice for the treatment of depression. Common side effects include gastrointestinal disturbance, agitation (especially early in treatment), and sexual dysfunction. Note that patients with psychotic depression rarely respond to antidepressants alone and require either the addition of an antipsychotic drug or a course of electroconvulsive therapy (ECT).

Although in general, SSRIs are as effective as TCAs and MAOIs in mild to moderate depression, TCAs and MAOIs introduced in the 1960s are often still used for patients who do not respond to one or more of the newer medications. The relative reluctance to use TCAs and MAOIs is due to issues of tolerability and/or serious side effects as well as their potential lethality if used in a suicide attempt. The most common adverse reactions when using TCAs are mainly due to cardiovascular and anticholinergic side effects.

As with any medication, drug interactions may occur, and cross-checking for these is key. MAOIs have important, life-threatening interactions with several drugs as well as interactions with food and, therefore, dietary precautions are essential.

A family history of effective drug response or previous response to a medication may be used to inform treatment selection. It is best with most medications to start with a low dose and increase slowly. Full benefit may take up to 4 to 6 weeks. After an initial episode, treatment should continue for 6 to 9 months at full dosage after the acute phase in order to prevent relapse.

Symptomatic relief with treatment may not result in immediate improvement of psychosocial function, which may be delayed. Relapses occur in up to 20% of patients in 6 months and over 30% in 1 year according to Keller. The risk of recurrence increases by 16% with each recurrent episode. The high rates of relapse have led to recommendations of maintenance treatment with drug therapy and prophylactic psychotherapy for patients with at least two episodes of depression LEVEL 1.[8,9]

Fifty percent to 60% of patients respond (50% improvement or better) to an initial course of antidepressant. However, remission (return to baseline or near baseline) is harder to attain and only about a third of patients remit after a first antidepressant treatment, requiring use of a different medication or augmentation strategies (see the following text).

Depression is often resistant to treatment. Several strategies have been developed to overcome this issue, such as combining antidepressants or augmenting antidepressant efficacy by adding other drugs such as lithium, stimulants (eg, dextroamphetamine or methylphenidate), antipsychotics, buspirone, or thyroid hormone. Empirical data driving decision making around intervention selection for treatment-resistant depression is still lacking. Studies comparing outcomes have not shown an advantage for any of the augmentation or second-tier strategies described thus far.

The past two decades have seen a growing or renewed interest in neuromodulation treatments, TMS and ECT LEVEL 1.[10-12]

TMS has been approved for the treatment of resistant depression, with response rates of around 60%.

It is a very safe and well-tolerated treatment, with less than 5% discontinuation. The most common side effect is mild temporary headache and discomfort in the application site. Its most serious side effect is seizures occurring during the sessions. Seizures are very uncommon; less than 0.1% during the complete treatment course. Unlike with ECT, there is no cognitive or memory loss, and it does not require general anesthesia for its application. At this point, there is no maintenance regimen approved by the U.S. Food and Drug Administration, and there are no clear guidelines.

Electroconvulsive treatment is indicated for patients with the following characteristics:

1. Failure to respond to adequate antidepressant pharmacotherapy trials
2. Depression with psychotic or catatonic features
3. Actively suicidal patients or manic patients so severely agitated that they must be rapidly controlled
4. Intolerance of side effects, as can happen in patients with PD, or allergies to multiple antidepressants
5. Inability to participate in pharmacotherapy or psychotherapy due to refusal to eat or drink or markedly slowed speech and cognition

ECT is a safe treatment and generally well tolerated. The most common side effect is mild, temporary memory loss. Because it is administered under general anesthesia, risks associated with anesthesia are also present. With proper medical preparation and screening, treatments may be administered even in the presence of neurologic or cardiovascular conditions. At the end of the course of treatment, a maintenance regimen must be instituted to prevent relapse. This can take the form of antidepressant medications, usually in combination, or "maintenance" ECT, generally administered monthly.

Treatment of Bipolar Disorders

Mood stabilization treatment is the gold standard for bipolar disorders LEVEL 1.[13-16] It serves to both control acute phases of the disease and prevent future episodes. Lithium is a potent antimanic. Remission is achieved in about 60% to 70% of cases, especially for patients with euphoric mania and infrequent episodes, although it takes several weeks to fully exert its therapeutic benefits. Lithium therapy requires regular blood level monitoring to prevent toxicity, which manifests at higher levels and can be life-threatening. Agitated and medically ill patients are at increased risk for toxicity. Lithium can cause hypothyroidism in 10% to 20% of patients and is relatively contraindicated in renal disease. Tremor is a common side effect.

Anticonvulsants such as valproate or carbamazepine can be used with good results in dysphoric mania or rapid cycling. They are often combined with lithium. Mood stabilization with second-generation antipsychotics (olanzapine, quetiapine, risperidone, or lurasidone) LEVEL 1,[17,18] is usually quicker and may also be more effective when psychotic symptoms are present. Sedating agents can also be used as adjunctive therapy for rapid control of agitation. The anticonvulsant lamotrigine has been shown to prevent recurrence of depression, but the data on its ability to control manic or hypomanic phases is weak.

In the case of bipolar depression, treating a depressive episode with antidepressants alone carries the risk of inducing to mania or hypomania. Nonetheless, aggressive treatment of depression is essential in bipolar disorder because it is in this phase that suicidal behavior occurs. Thus, although less dramatic than mania, it is certainly just as dangerous, if not more. Using mood stabilizers alone is only effective in a few cases. Most commonly, bipolar depression is treated with a combination of antidepressants and mood stabilizers. Quetiapine and lurasidone both have antidepressant effects and are U.S. Food and Drug Administration approved for monotherapy in bipolar depression.

Manic relapse may be spontaneous, induced by therapeutic drugs, or induced by substances. With continued use of a mood stabilizer, the risk of antidepressant-induced mania is about 10%. Data suggest that newer antidepressants are less likely than tricyclics or MAOIs to precipitate manic "switches."

After the second bipolar episode, regardless of polarity, patients should be treated indefinitely because relapse is almost certain. The treatment goal is to maintain euthymia and prevent either depression or manic episodes. Lithium has been the prophylactic drug of choice for decades, but the antipsychotic mood stabilizers are also approved for long-term prophylaxis. Consideration of side effect profiles as well as therapeutic benefits is essential when considering treatment selection.

Treatment of Mood Disorders Comorbid With Neurologic Disorders

Patients with dementia frequently develop psychiatric symptoms, including depression, elation, delusions, hallucinations, and periods of extreme irritability, agitation, or disinhibition. Dementia may be accompanied by full-blown psychiatric syndromes. These episodes are often brief. Nevertheless, modest doses of antidepressants may be of use. Side effects may be minimal with low doses. Antipsychotic medications must be used with extreme care but may be useful to treat agitation. They may induce extrapyramidal symptoms, especially the conventional ones.

Significant clinical depression occurs in 40% to 50 % patients with PD. The depressive symptoms respond well to low doses of antidepressants including the SSRIs. Occasionally, SSRI therapy increases parkinsonism, especially sertraline at higher doses, wherein the drug's selective affinity for 5-HT transporters is obviated. ECT is safe and effective and may improve both the depression and the motor symptoms of PD. In the case of HD, manic symptoms should be treated with the usual medications but often require smaller (one-third to one-half) doses. At times, ECT may be lifesaving. Treatment of mood disorders associated with epilepsy depends on whether the episode in question is ictal, peri-ictal, or interictal. When the mood disorder is ictal or peri-ictal, the focus of the treatment is the epileptic disorder with antiepileptic medications, and when it is interictal, the focus of the treatment is the depressive disorder with antidepressants. Drugs used to treat mood disorders, including for example, lithium or valproic acid may cause or exacerbate tremor. See **Table 154.2** for a list of neurologic adverse effects of common drugs used to treat mood disorders.

OUTCOME

Mood disorders are a major cause of disability and are highly associated with poor psychosocial functioning, mainly due to depressive episodes, which are much more common and longer lasting.

First-onset MDD typically peaks from ages 14 to 19 years, although first depressive episodes can appear at any age. If untreated, an episode lasts on average 6 to 9 months. Fifty percent to 70% of patients with major depression have recurrent episodes in their lifetimes. Young age, presence of a severe preceding episode,

TABLE 154.2 Neurologic Side Effects Associated With Drugs Used for Mood Disorders Treatment

Side Effect	Drug
Seizures	(All antidepressants and antipsychotics can potentially induce seizures.)
	Bupropion
	Maprotiline
	Amoxapine
	Imipramine
	Escitalopram
	Clozapine
	Selegiline
Tremor	Bupropion
	Lamotrigine
	SSRIs
	Antipsychotics (especially first generation)
	Phenelzine
	Trazodone
	Lithium
	Valproic acid
Akathisia	Aripiprazole and other antipsychotics
	SSRIs
Dyskinesia	Selegiline
Tardive dyskinesia	Antipsychotics
Cerebrovascular events	Increased risk with second-generation antipsychotics in elderly
Headaches	Trazodone
	Venlafaxine
Ataxia	Lamotrigine
	Nefazodone
Aseptic meningitis	Lamotrigine (rare)

Abbreviation: SSRIs, selective serotonin reuptake inhibitors.

persistence of even mild depressive symptoms, and a history of multiple episodes increase the likelihood of recurrence. Symptom profiles can often change from one episode to another. Around 12% to 20% of patients will present a chronic course. Risk factors for chronicity include a strong family history of depression, older age, longer duration of illness before treatment is sought, alcoholism, medical illness, disability of spouse, or multiple recent deaths of family members.

Bipolar disorder usually has an earlier age of onset than major depression. The first episode is more frequently depressive, with a peak incidence at age 17 years. Late-onset bipolar disorder is rare and is usually associated with organic disease. Mania typically ensues within 5 years of the first depressive episode.

In terms of the polarity of episodes, very few patients present only recurrent manic episodes with little or no depression. Rather, depressive episodes and symptoms tend to dominate the longitudinal course of bipolar disorder. Bipolar disorder can also vary in terms of the frequency of episodes. Almost all patients with bipolar disorder have recurrent episodes, and episodes are more frequent and numerous than in depressive disorders. In some cases, patients may experience four or more mood episodes in a year, termed *rapid cycling*. Once thought to be a characteristic of the patient, rapid cycling can occur and later resolve itself with a return to less frequent episodes.

Bipolar patients usually function well when medicated. Nevertheless, although many patients are able to resume normal activities within several weeks to months after recovery, approximately 40% of patients have significant social dysfunction for up to 2 years after an episode. Persistent cognitive deficits are documented as well. Neurobiologic deterioration from repeated episodes may play a role in this phenomenon.

Suicide is the most dreaded outcome of mood disorders. The suicide rate in bipolar illness is higher than in any other psychiatric illness, responsible for the death of 8% to 15% of patients, and patients with bipolar disorder carry a 15-fold greater risk of suicide than the general population. Risk is even greater in the case of comorbidity with substance abuse disorders. Specific interventions for suicidal behavior such as Safety Planning Intervention and Cognitive Therapy for Suicidal Behavior are potential options to address risk and mood stabilization and aggressive management of depression can be lifesaving.

155 Anxiety Disorders, Posttraumatic Stress Disorder, and Obsessive-Compulsive Disorder

Franklin R. Schneier

KEY POINTS

1. Anxiety disorder features take the form of fearful thoughts, physical symptoms of anxiety, and phobic avoidance behaviors.
2. Within neurologic disorders, comorbid anxiety disorders are associated with greater distress and impairment in functioning.
3. Posttraumatic stress disorder commonly co-occurs with traumatic brain injuries.
4. Obsessive-compulsive disorder commonly co-occurs with tic disorders.
5. The best established treatments for anxiety disorders, posttraumatic stress disorder, and obsessive-compulsive disorder are cognitive behavioral therapies and serotonin reuptake inhibitor medications.

INTRODUCTION

Anxiety is an adaptive emotional state related to anticipation of threat; it can encompass fearful thoughts, symptoms of physiologic arousal, and preparation for fight or flight. *Anxiety disorders* are characteristic syndromes of maladaptation to various types of anticipated threat. Examples include dangers from predators, interpersonal conflicts, germs, and other hazards. Anxiety disorders are distinguished from mild episodes of anxiety by their persistence and intensity and also by the diagnostic requirement that they cause marked distress or impairment in functioning.

Anxiety disorders have historically included panic disorder, agoraphobia, specific phobias, social anxiety disorder, generalized anxiety disorder, obsessive-compulsive disorder (OCD), acute stress disorder, and posttraumatic stress disorder (PTSD). The *Diagnostic and Statistical Manual of Mental Disorders* (5th edition, *DSM-5*), places OCD in a separate category of obsessive-compulsive and related disorders and PTSD in a separate category of trauma- and stressor-related disorders, in recognition of their unique features. Two disorders previously categorized as childhood disorders, separation anxiety disorder and selective mutism, are now also recognized as anxiety disorders that can persist into adulthood.

Anxiety and anxiety disorders may co-occur with neurologic disease through a variety of mechanisms. Neurologic disease processes may cause anxiety symptoms directly by dysregulating function of brain circuits that subserve anxiety. Alternatively, primary neurologic illnesses may lead to anxiety via psychological mechanisms as when visible signs of a movement disorder lead to embarrassment and social anxiety or when an uncertain or poor prognosis leads to anticipatory anxiety. A primary anxiety disorder or its treatment may generate neurologic manifestations, such as syncope secondary to hyperventilation in panic disorder, or a seizure due to abrupt discontinuation of a benzodiazepine. Neurologic and psychiatric conditions may also co-occur secondary to another causal agent as when combat trauma leads to both traumatic brain injury (TBI) and PTSD.

EPIDEMIOLOGY

The broad category of anxiety disorders constitutes the most common type of psychiatric disorder with a lifetime prevalence of over 25%. Anxiety disorders are more common in women by a 2:1 ratio, have an age of onset before 30 years in most cases, and tend to be chronic. Community prevalence rates for individual anxiety disorders range from 5% to 12% for social anxiety disorder and specific phobias to 1% to 2% for panic disorder and OCD, with intermediate rates for PTSD and generalized anxiety disorder.

PATHOBIOLOGY

The neural circuits, neurochemistry, and behaviors mediating human anxiety share features with neural systems that mediate withdrawal responses to aversive stimuli across species. In humans, these responses incorporate higher cortical functions such as anxious anticipation and adaptations based on life experiences and culture. Twin studies show heritability of specific anxiety disorders in the range of 10% to 60%, but findings for individual genes explain only very small proportions of the overall risk. Environmental risk factors for anxiety disorders include early childhood trauma and acute stressors, such as interpersonal loss.

Studies in rodents and humans have implicated dysregulation of central nervous system fear circuitry, including the amygdala, hippocampus, and prefrontal cortex, in the development and maintenance of conditioned fear; this circuitry is activated when persons with social anxiety disorder, specific phobias, or PTSD are exposed to fear-inducing stimuli. Related processes include fear memory consolidation, generalization, and extinction. PTSD has been associated with dysfunction across salience, executive, and default mode networks (Fig. 155.1). Anxiety disorders also have been shown to be associated with a proinflammatory milieu and with dysfunction of several neurotransmitter systems, including serotonin, norepinephrine, γ-aminobutyric acid, and

FIGURE 155.1 Network-based neurobiologic model of posttraumatic stress disorder. The figure shows the cortical representations of the salience network (SN; *orange*), default mode network (DMN; *red*), and central executive network (CEN; *blue*) in healthy individuals; notable region of interests within these networks; the changes in posttraumatic stress disorder predicted by the model; and the putative resulting phenotypic abnormalities. Abbreviations: dACC, dorsal anterior cingulate cortex; dlPFC, dorsolateral prefrontal cortex; MTL, medial temporal lobe; PCC, posterior cingulate cortex; vmPFC, ventromedial prefrontal cortex. The *asterisk* denotes altered between-network connectivity. (From Akiki TJ, Averill CL, Abdallah CG. A network-based neurobiological model of PTSD: evidence from structural and functional neuroimaging studies. *Curr Psychiatry Rep.* 2017;19:81.)

glutamate. Dopamine dysfunction has also been reported, and elevated rates of panic disorder, generalized anxiety disorder, and social anxiety disorder have been reported in Parkinson disease. Sympathetic nervous system and hypothalamic-pituitary axis abnormalities have been found across anxiety disorders. Panic disorder has been associated with hyperventilation, hypocapnia, and disordered carbon dioxide regulation.

The pathobiology of OCD shows some differences from other anxiety disorders. Anatomic and brain imaging evidence suggest hyperactivity in a circuit involving the orbitofrontal cortex, basal ganglia, and thalamus. Acquired lesions in the cortico-striato-thalamic circuit, parietal and temporal cortex, cerebellum, and brainstem have been reported to induce compulsivity. OCD has been associated with other neurologic conditions involving the basal ganglia, such as Tourette syndrome, Huntington disease, and Sydenham chorea.

DIAGNOSIS

Clinical Features Across Anxiety Disorders

Anxiety disorder patients may present with anxiety, avoidance, physical symptoms, secondary depression, or substance abuse. Complaints of anxiety should be assessed with respect to symptoms and cognitions, frequency and intensity, environmental

precipitants, avoidance, and interference with functioning. Some anxiety disorder features can occur across these disorders. *Anticipatory anxiety* refers to apprehension in anticipation of a feared situation and may include worry, difficulty concentrating, or physical symptoms. Anxiety disorders are often marked by a failure of the habituation that normally occurs during continuing exposure to a feared situation. A *panic attack* is defined by intense fear that reaches a peak in minutes and includes a group of physical anxiety symptoms, often with feelings of unreality, dizziness, paresthesias, dyspnea, and fear of dying. *Phobic avoidance* involves excessive avoidance of circumscribed feared situations, and it is often the most directly disabling of anxiety disorder features.

Anxiety often leads to symptoms of depression, so anxious patients should be evaluated for depressed mood, loss of pleasure, change in weight, sleep disturbance, fatigue, poor concentration, and suicidal ideation. Substance abuse is also common in anxiety disorder patients and may be either a precipitant of anxiety or a response to it. People with anxiety disorders are usually aware that the symptoms are related to an excessive or unrealistic reaction on their part, and in this way, they differ from patients with psychotic disorders with delusional fears.

Anxiety disorders may interact with other medical conditions so that patients with asthma may also experience dyspnea related to panic attacks, and individuals with disorders that attract unwanted attention (eg, essential tremor) may be impaired by excessive fear of embarrassment as in social anxiety disorder. Medical conditions that can directly mimic anxiety symptoms include hyperthyroidism; hyperparathyroidism; cardiac arrhythmias; reactions to caffeine, cocaine, or marijuana; pheochromocytoma; and vestibular dysfunction.

See **Table 155.1** for key diagnostic features.

TABLE 155.1 Key Diagnostic Features of Anxiety Disorders

Diagnosis	Key Diagnostic Features
Panic disorder	Recurrent unexpected panic attacks
Agoraphobia	Avoidance of situations where escape might be difficult in the event of experiencing panic-like symptoms
Social anxiety disorder	Persistent and excessive fears of negative evaluation in social or performance situations
PTSD and acute stress disorder	After a traumatic event, persistent intrusive thoughts, avoidance of reminders, dysphoria, and hyperarousal
Obsessive-compulsive disorder	Obsessive thoughts and repetitive compulsive behaviors
Generalized anxiety disorder	Excessive anxiety and worry about multiple issues
Specific phobia	Persistent and excessive fear of a specific object or situation
Separation anxiety disorder	Persistent and excessive fear of separation from an attachment figure
Selective mutism	Persistent failure to speak in specific social situations (eg, school); usually seen in young children

Abbreviation: PTSD, posttraumatic stress disorder.

Panic Disorder and Agoraphobia

The essential feature of panic disorder, as described in *DSM-5*, is recurrent unexpected panic attacks followed by persistent concerns or significant changes in behavior related to fear of another attack. Patients with panic disorder are often first seen medically because of fears that they are having a heart attack or stroke. Panic attacks may become cued by specific situations most commonly involving situations in which the person anticipates difficulty escaping or getting help in the event of an attack, such as traveling away from home, being in a crowd, or being alone. When people fear and avoid such situations, the diagnosis of agoraphobia is made.

Panic Disorder Case Example

A 23-year-old woman presented to the emergency department complaining of 1-hour duration of light-headedness, weak legs, difficulty breathing, tingling sensations in her hands, and fear that she was having a stroke. Symptoms came on suddenly with no specific trigger, although she was feeling stressed after having had an argument with her boyfriend yesterday. Medical and neurologic evaluation was unremarkable. The patient was told that her symptoms were due to anxiety, and they subsequently resolved over a couple of hours. However, the patient developed daily recurrences of attacks over the next week, with fear that the symptoms would be persistent and disabling, even if they were not life-threatening. She called in sick to work and asked a family member to stay with her. Following 8 weeks of treatment with a selective serotonin reuptake inhibitor (SSRI) medication and cognitive behavioral therapy (CBT), her panic attacks remitted, although she continued to experience occasional brief surges of mild anxiety.

Social Anxiety Disorder (Social Phobia)

Social anxiety disorder, also known as *social phobia*, is characterized by an excessive fear of social situations due to fears of negative evaluation. The person may avoid social or performance situations or endure them with great distress. Physical symptoms, such as sweating, tremor, and blushing, may be present, but they are not necessary for the diagnosis as per *DSM-5*. The scope of feared situations may encompass most situations and appear similar to extreme shyness or may be limited to performance situations, such as public speaking. Social anxiety disorder is distinguished from normal shyness by its greater persistence and severity and its associated distress or impairment. Persons with social anxiety disorder often have difficulty participating in classroom settings or work meetings, dating, or engaging in social gatherings.

Posttraumatic Stress Disorder and Acute Stress Disorder

Stress disorders occur in persons exposed to a traumatic event in which the person experienced, witnessed, or was confronted with actual or threatened death, serious injury, or sexual violence to self or others. PTSD features according to *DSM-5* include more than 1 month of (1) intrusive memories, dreams, or flashbacks or intense psychological and physiologic distress at exposure to reminders of the trauma; (2) avoidance of stimuli associated with the trauma; (3) alterations in cognition or mood, such as self-blame or inability to experience positive emotions; and (4) symptoms of increased arousal, such as hypervigilance,

insomnia, poor concentration, irritability, or reckless behavior. Acute stress disorder is diagnosed when a similar syndrome is present in the month after trauma exposure, and it may progress to PTSD. Only a minority of serious traumatic events, however, result in development of PTSD. Trauma-related disorders are more likely to occur following stressors of an interpersonal nature (eg, physical or sexual assault) relative to noninterpersonal trauma (motor vehicle accident or natural disaster), and after repeated stressors.

PTSD Case Example

A 26-year-old woman army veteran was referred to treatment by her family after they observed that since return from deployment she seemed detached and unmotivated to pursue work or social activities. During her initial evaluation, she reported intrusive recollections of a sexual assault that had occurred 1 year ago during her service but that she had never reported or discussed with anyone. She had continued to function well until leaving the military, at which time she began to feel detached from her friends and family, and fearful in situations around unfamiliar men. She startled easily to noises and slept poorly. She felt "damaged" and saw no future for herself, but she did not have any active suicidal ideation. She began trauma-focused CBT, in which she recounted details of her trauma, and discussed its meanings for how she viewed herself and the safety of social situations. She experienced high anxiety during the first several therapy sessions but soon reported diminished symptoms, and she gradually was able to resume social activities and pursue employment.

Obsessive-Compulsive Disorder

OCD is defined in *DSM-5* by recurrent obsessions or compulsions that are time-consuming (more than 1 h/d) or cause significant distress and impairment. Obsessions are recurrent and persistent thoughts, urges, or images that are experienced as intrusive and unwanted and cause marked anxiety or distress. The individual attempts to ignore or suppress the obsessions or to neutralize them with some other thought or action. Insight into the truth of obsessive beliefs may vary. Compulsions are repetitive behaviors, such as washing or checking, or mental acts, such as counting, that an individual feels driven to perform in response to an obsession or according to rigid rules. The individual may have ideas that the behaviors prevent distress or that they somehow prevent a dreaded event (eg, death of a loved one). However, these behaviors are not realistically connected with what they are intended to prevent, or they are clearly excessive. Up to 30% of individuals with OCD have a lifetime tic disorder, and in such cases, the diagnosis should be specified as *tic related*.

Generalized Anxiety Disorder

Generalized anxiety disorder is characterized, according to *DSM-5*, by excessive anxiety and worry about a number of events or activities occurring more days than not for at least 6 months. The individual finds it difficult to control the worry, which is associated with three or more of (1) restlessness or feeling keyed up, (2) fatigue, (3) difficulty concentrating, (4) irritability, (5) muscle tension, and (6) sleep disturbance. Generalized anxiety disorder is highly comorbid with depression.

Specific Phobias

Persons with a specific phobia exhibit persistent fear of a specific object or situation, exposure to which evokes a fear response out of proportion to the actual danger. As specified in *DSM-5*, common types are the following: animal (eg, spiders or dogs), natural environment (eg, storms, heights), situational (eg, airplanes, enclosed places), and blood-injection-injury (eg, needles, dentist). A vasovagal response has been specifically associated with blood-injection-injury phobia.

Separation Anxiety Disorder

Separation anxiety disorder is characterized in *DSM-5* by an excessive fear of separation from an attachment figure as evidenced by at least three of the following: excessive distress related to separation, excessive worry about harm to an attachment figure, excessive worry about an untoward event that results in separation, reluctance to go out (eg, to work), reluctance to be alone, reluctance to sleep away from an attachment figure, nightmares about separation, and physical symptoms when separated. Adults often worry about a significant other or a child.

Selective Mutism

Selective mutism is generally diagnosed in young children but may persist into adulthood. As described in *DSM-5*, the diagnosis is based on observation that an individual manifests a persistent failure to speak in specific social situations (eg, school) despite speaking in other situations. The behavior interferes with functioning and is not due to a lack of knowledge of the spoken language or a communication disorder (eg, childhood-onset fluency disorder). A child with selective mutism may be unable to offer an explanation for his or her silence, although high levels of social anxiety often appear to be associated with this reticent behavior.

Anxiety and Neurologic Disease: Comorbidity and Differential Diagnosis

Anxiety disorder symptoms can overlap greatly with symptoms of a variety of neurologic disorders, including movement disorders, epilepsy, or cerebrovascular disease. For example, tremor is a common manifestation of anxiety, and it is particularly common in performance situations for individuals with social anxiety disorder. Light-headedness, occasionally even leading to syncope, is common during panic attacks. Panic-related light-headedness is usually of short duration and accompanied by dyspnea, hyperventilation, and intense fear. Paresthesias, tinnitus, vertigo, impaired concentration, derealization, and depersonalization may also occur during panic attacks or other periods of high anxiety. Importantly, the presence of psychopathology does not rule out the presence of concurrent neurologic disorder, and symptoms of a primary neurologic disorder, such as tremor or vertigo, may be exacerbated by situational anxiety. When a comorbid anxiety disorder complicates a neurologic disorder, treatments targeted at each condition may be necessary.

PTSD in veterans has been associated with neurologic and cognitive problems, as in Gulf War illness. Mild TBI in civilians was associated with an approximately twofold increased risk of PTSD 3 to 6 months later compared to a group with nonhead injuries. When a TBI co-occurs, PTSD symptoms may overlap TBI-related neurocognitive symptoms.

Obsessive-compulsive symptoms have been specifically associated with several neurologic disorders sharing dysfunction of frontostriatal circuitry, including Huntington disease, Sydenham chorea, and Gilles de la Tourette syndrome. OCD shares genetic heritability with Tourette syndrome. In patients with

Huntington disease, obsessive-compulsive symptoms, particularly obsessive checking, pathologic impulses, and compulsive rituals, have been reported in 15% to 50% of cases. OCD symptoms are also elevated in persons with the genetic mutation for Huntington but who have not yet met criteria for the diagnosis.

Tics have a compulsive quality, and like compulsions, if resisted, they result in internal tension that is relieved by performance of the behavior. The compulsions of OCD, however, are often accompanied by a complex thought process (eg, need to relieve a sense of contamination) that seems to motivate the compulsive behavior. Compulsions that are present in patients with Tourette syndrome tend to be related to symmetry, counting, or "just right" thoughts and less likely to relate to fears of contamination or harm to others. Pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections and more recently the broader category of pediatric acute neuropsychiatric syndrome are controversial variants of childhood-onset OCD and neurologic disorders such as tics disorders, in which both conditions may be associated with the development of an immune response against group A β-hemolytic *Streptococcus*, or other triggers.

In epilepsy, and particularly refractory focal epilepsy, there is an increased rate of anxiety disorders, impacting quality of life. Interictal anxiety symptoms may include anticipatory anxiety about having a seizure, phobic avoidance of situations in which seizures have occurred, and fears of being seen by others during a seizure. Panic disorder symptoms are the anxiety symptoms most likely to be generated directly by a seizure and may be challenging to distinguish from primary panic attacks. Patients with primary panic attacks are less likely than seizure patients to experience automatisms, impaired consciousness, or déjà vu experiences and more likely to have accompanying phobias, depression, and anticipatory anxiety.

Dementia is accompanied by rates of anxiety as high as 75%, often in the form of generalized anxiety disorder symptoms. Rates of anxiety symptoms may be particularly greater in vascular dementia and frontotemporal dementia. The presence of anxiety in dementia is associated with a variety of worse outcomes, including more impairment in quality of life, activities of daily living, nighttime awakenings, and neuropsychological performance. Additionally, PTSD has been associated with increased risk for dementia.

Males with the genetic syndrome fragile X commonly experience symptoms of multiple anxiety disorders, particularly social anxiety symptoms of poor eye contact and excessive shyness. They also have elevated rates of separation anxiety, panic attacks, and agoraphobia. Compulsive behaviors are present in most patients, but these often involve pleasurable activities rather than the unwanted compulsions characteristic of OCD.

In patients with multiple sclerosis, anxiety disorders occur at three times the rate of the general population. Generalized anxiety disorder, OCD, panic disorder, and social anxiety disorder have been found to be elevated in some studies. Anxiety is associated with confirmed exacerbations and pseudoexacerbations of multiple sclerosis and with greater impairment and lower quality of life, although it has not been specifically linked to progression of brain lesions.

Anxiety symptoms are common during a stroke, and in the first year poststroke the prevalence of anxiety disorders is greater than 25%, with anxiety often related to fear of stroke recurrence.

Neurologic symptoms that attract unwanted attention, such as tremor or dystonia, may result in elevated fears of embarrassment. For some patients, the social anxiety may lead to avoidance and greater impairment than that of the underlying disorder. When social anxiety is out of proportion to the severity of the underlying condition, diagnosis and treatment of social anxiety disorder may be warranted.

MANAGEMENT

General Approaches to Anxiety Disorders

Psychological and pharmacologic treatments (Table 155.2) have well-established efficacy for anxiety disorders. The two best established first-line treatments for most of the anxiety disorders are CBT and SSRI medications, based on dozens of controlled trials in specific anxiety disorders. Other psychotherapies, such as short-term psychodynamic therapies, and other medications, such as benzodiazepines, have been demonstrated efficacious in certain anxiety disorders. This section describes the general features of CBT and classes of medication used for anxiety disorders as well as their unique adaptations for specific anxiety disorders.

CBTs for anxiety disorders are short-term psychotherapies based on the observation that patients manifest cognitive distortions (irrational negative thoughts) that maintain anxiety and avoidance behaviors, and that deny them opportunities to disprove those fears or to experience habituation of anxiety symptoms. Components of this therapy may include cognitive restructuring, exposure, and relaxation techniques. Typically, an active therapist helps the patient identify his or her cognitive distortions and avoidance behaviors and introduces alternative approaches for coping with feared situations. Therapist and patient collaborate to conduct exposures to the feared situations in the presence of the therapist and through homework assignments. As the patient uses new coping skills to manage the anxiety induced by the exposure without resorting to avoidance or rituals, new learning takes place and the habitual cycle of fear and avoidance recedes. A far smaller body of evidence exists for efficacy of other psychotherapy approaches to anxiety, including psychodynamic therapy. Disorder-specific features of CBT and other psychotherapies are discussed in the following text under specific anxiety disorder sections.

SSRIs and serotonin-norepinephrine reuptake inhibitors (SNRIs) have emerged as first-line treatments for each of the anxiety disorders (with the exception of specific phobias) based on efficacy and acceptability. No single SSRI has been shown to be superior to others, although individuals often have different responses to different agents. Dosages are similar to those recommended for treatment of depression. Responses typically become apparent after 2 to 4 weeks of treatment, but an adequate acute trial may require 8 to 12 weeks of treatment, and nonresponders should have the dosage gradually increased to the maximum as tolerated. Common side effects include nausea, insomnia, fatigue, weight gain, and sexual dysfunction. Treatment guidelines tend to recommend that responders to an acute trial of medication be maintained on the effective dose for 6 to 12 months, and when medication is discontinued, it should be tapered to minimize risk of withdrawal symptoms and relapse.

Medication is commonly combined with CBT, although evidence for additive efficacy is limited. Other medications, including some classified as benzodiazepines, tricyclic antidepressants, monoamine oxidase inhibitors, anticonvulsants, and antipsychotics, have also been shown to be effective for some of the anxiety disorders. These are discussed where relevant in the following text under specific anxiety disorder sections.

TABLE 155.2 Medications Used in the Treatment of Anxiety Disorders

Medication	Initial Dose (mg/d)	Target Dose (mg/d)	Indication LEVEL 1
Selective Serotonin Reuptake Inhibitors			
Sertraline	50[a]	50-200	OCD,[1] PD,[2] SAD,[3] PTSD,[4] GAD[5]
Paroxetine	10[a]	10-60	OCD,[1] PD,[2] SAD,[3] PTSD,[4] GAD[6]
Paroxetine CR	12.5[a]	12.5-75	SAD[3]
Citalopram	10[a]	20-40	PD,[2] OCD[1]
Escitalopram	5[a]	5-20	GAD[6]
Fluvoxamine	50[a]	50-300	OCD,[1] PD,[2] SAD[3]
Fluoxetine	20	20-80	OCD,[1] SAD,[3] PTSD[4]
Serotonin-Norepinephrine Reuptake Inhibitors			
Venlafaxine XR	75[a]	75-375	SAD,[3] PD,[2] PTSD,[4] GAD[6]
Duloxetine	30[a]	30-60	GAD[6]
Other Antidepressants			
Nefazodone	200	200-600	PTSD[4]
Mirtazapine	15	30-60	SAD,[3] PD[2]
Clomipramine	25	50-250	OCD,[7] PD[8]
Imipramine	25	50-300	PD[9]
Phenelzine	15	30-90	SAD[3]
Benzodiazepines			
Clonazepam	0.25	0.5-4	SAD,[3] PD[10]
Alprazolam	0.25	0.5-6	PD,[10] GAD[11]
Lorazepam	0.5	1-2	GAD[11]
Diazepam	5	20	GAD[11]
Other Classes			
Buspirone	10	30-60	GAD[12]
Hydroxyzine	25	50	GAD[6]
Gabapentin	600	900-3,600	SAD[3]
Pregabalin	300	600	SAD,[3] GAD[6]
Prazosin	1	2-6	PTSD[13]
Risperidone	0.5	0.5-6	PTSD[4]
Quetiapine ER	50	50-300	GAD[14]

Abbreviations: CR, controlled release; ER, extended release; GAD, generalized anxiety disorder; OCD, obsessive-compulsive disorder; PD, panic disorder; PTSD, posttraumatic stress disorder; SAD, social anxiety disorder; XR, extended release.
[a]For PD, antidepressants are commonly initiated at half the usual initial dose.

Panic Disorder and Agoraphobia

CBT for panic and agoraphobia has been shown efficacious in multiple randomized controlled trials (RCTs) LEVEL 1.[15] It helps patients decatastrophize their beliefs about physical symptoms through cognitive restructuring and interoceptive exposure, which involves purposefully inducing feared physical symptoms (eg, by exercise or hyperventilation). Patients with agoraphobia purposefully approach their feared situations. Among pharmacologic treatments for panic disorder, SSRIs LEVEL 1[2] and SNRIs LEVEL 1[2] are first-line treatments. Benzodiazepines LEVEL 1,[10] the antidepressant mirtazapine LEVEL 1,[2] and the older class of tricyclics (eg, imipramine) LEVEL 1[9] and clomipramine LEVEL 1[8] have also been shown to be efficacious. Antidepressants are typically started at half of the usual starting dose because some panic disorder patients will report excessive stimulation with initial dosing. Benzodiazepines are often prescribed on an as-needed basis for intermittent anxiety, but for panic disorder and social anxiety disorder (see the following section), they are most effectively used with standing doses. Alprazolam and clonazepam are the benzodiazepines that have been best studied in panic disorder. Benzodiazepines have rapid onset of effect and a relatively low rate of side effects other than sedation. They are sometimes used in combination with SSRIs. Disadvantages include potential for abuse, cognitive and motor impairment, risk of severe withdrawal symptoms if discontinued abruptly, and lack of efficacy for comorbid depressive symptoms.

Social Anxiety Disorder

CBT LEVEL 1[15] is effective in either individual or group formats, incorporating role-playing techniques to practice exposure to feared social scenarios. SSRIs and the SNRI venlafaxine are first-line treatments based on numerous RCTs LEVEL 1.[3] A smaller number of RCTs support use of the benzodiazepine clonazepam; the antidepressant

mirtazapine, gabapentin, and pregabalin, which act at calcium channels; and the older antidepressant class of monoamine oxidase inhibitors (eg, phenelzine) LEVEL 2.[3] β-Adrenergic blockers (eg, propranolol), taken on an as-needed basis, are commonly used for anxiety that is limited to predictable performance situations.

Posttraumatic Stress Disorder and Acute Stress Disorder

Efficacy of CBT for acute stress disorder and PTSD has been established by more than two-dozen controlled trials LEVEL 2.[15] Goals of psychotherapy for acute stress disorder are to reestablish a sense of safety, build a therapeutic alliance, provide information, and allow ventilation of emotion only after the perceived threat ends. Treatment of PTSD involves education about the normal course of stress response, relaxation techniques, cognitive therapy to address pathogenic beliefs, and exposure to trauma-related stimuli through imaginal techniques, such as reviewing a script of the trauma, and through in vivo exposure.

Pharmacologic treatments for PTSD are used primarily as an adjunct to psychotherapy. The SSRIs paroxetine, fluoxetine, and sertraline and the SNRI venlafaxine, each have a few RCTs supporting efficacy LEVEL 2.[4] Benzodiazepines, however, have not been shown to be effective. Single controlled trials have supported efficacy for the serotonergic antidepressant nefazodone LEVEL 2.[4] The α_1-antagonist prazosin has appeared efficacious in small trials, with specific benefit for nightmares LEVEL 2,[13] but a large trial in veterans failed to replicate these effects. Two very small RCTs have suggested efficacy for the atypical antipsychotic risperidone LEVEL 2.[4] Several RCTs suggest that transcranial magnetic stimulation may also be effective for PTSD LEVEL 2.[16]

Obsessive-Compulsive Disorder

Exposure and response prevention is the most effective treatment of OCD based on many controlled trials including comparisons to medication treatment LEVEL 2.[15] This CBT involves systematically exposing a patient to feared situations and preventing ritualizing (eg, touching dirt without washing, leaving home without checking the lock). Clinical trials report high response rates in patients who participate in this therapy.

SSRIs LEVEL 2[1] and the serotonergic tricyclic antidepressant clomipramine LEVEL 2[7] are the only established pharmacologic monotherapies for OCD. Patients may require maximal dosage and a 12-week trial to assess efficacy, and most patients achieve only partial benefit from these medications. The only pharmacologic augmentation strategy shown to be effective for partial responders to SSRIs, on the basis of several small RCTs, is the use of antipsychotic agents, such as haloperidol or risperidone LEVEL 2.[5] One small RCT has suggested efficacy for transcranial magnetic stimulation of the medial prefrontal and anterior cingulate cortices in treatment-refractory patients LEVEL 2.[6] Other small RCTs have suggested efficacy for deep brain stimulation to the ventral capsule/ventral striatum or the anteromedial subthalamic nucleus in treatment-refractory patients LEVEL 2.[12] Refractory OCD has also occasionally been treated neurosurgically by anterior cingulotomy, subcaudate tractotomy, or anterior capsulotomy.

Generalized Anxiety Disorder

CBT for generalized anxiety disorder has established efficacy LEVEL 2[15] and often incorporates self-monitoring of symptoms and their triggers, and relaxation techniques. In addition to SSRIs and SNRIs, which have established efficacy in multiple RCTs LEVEL 2,[11] other drugs with evidence for efficacy from RCTs include pregabalin LEVEL 2,[11] the serotonin 1A receptor agonist–antagonist buspirone LEVEL 2,[14] and antihistamines (eg, hydroxyzine) LEVEL 2.[11] Although benzodiazepines were once a mainstay for generalized anxiety, recent studies have questioned the quality of the early trials in generalized anxiety disorder that established efficacy of these medications LEVEL 2.[17] The antipsychotic quetiapine has appeared efficacious in several controlled trials but carries a risk of serious adverse effects, such as tardive dyskinesia LEVEL 2.[18] Several small RCTs have also suggested at least short-term efficacy of transcranial magnetic stimulation to the right dorsolateral prefrontal cortex or right parietal cortex LEVEL 2.[19]

Specific Phobias

Desensitization by exposure is the preferred treatment for specific phobias, and it is highly effective. Medications have received little study, but benzodiazepines, taken as needed, are useful for feared situations that are encountered only occasionally.

Separation Anxiety Disorder and Selective Mutism

There have been no controlled studies of treatment of either of these disorders in adults. Controlled trials in children suggest that both SSRIs and CBT are beneficial for separation anxiety disorder. Studies of selective mutism similarly suggest a role for SSRIs and CBT.

Treatment of Anxiety Disorders Comorbid With Neurologic Disorders

Although there is little data to guide approaches to these patients, existing studies suggest that standard treatments for the comorbid anxiety disorder can be effective in reducing anxiety symptoms and impairment. For example, CBT has been shown to reduce anxiety symptoms and social adjustment in epilepsy patients with mixed psychiatric problems even in the absence of reduction in seizure frequency. γ-Aminobutyric acid–ergic anticonvulsants such as benzodiazepines and pregabalin often benefit comorbid anxiety, and SSRIs can be used with only small effects on seizure threshold. In dementia, psychosocial interventions are preferred for anxiety because benzodiazepines and antipsychotics carry increased risks for the elderly and cognitively impaired. In Tourette syndrome, CBT and SSRIs, sometimes augmented with antipsychotics, should be considered for patients with comorbid OCD. In multiple sclerosis, self-management interventions incorporating CBT techniques have shown promise in reducing anxiety LEVEL 2.[20] Open trials for poststroke anxiety have suggested possible benefit for buspirone and for SSRIs plus psychotherapy, and a small RCT suggested benefit for self-help relaxation.

OUTCOME

Efficacious psychological and pharmacologic treatments have been well established for most of the anxiety disorders. CBTs have yielded response rates upward of 80% in some studies for those patients able to complete a course of treatment.

Response rates to an initial trial of SSRI medication typically range from 50% to 70%, but less than half of these responders attain remission. These same approaches appear to be useful for anxiety disorders that are comorbid with neurologic disorders. Research is ongoing into exploring anxiety disorder treatments with novel mechanisms, improving treatment selection through personalized medicine, and developing alternative strategies for patients who do not respond fully to first-line treatments.

Somatic Symptom Disorders 156

Anna L. Dickerman, Philip R. Muskin, and Vivian Liu

KEY POINTS

1. Somatic symptom disorder occurs when physical symptoms distressing to the patient are also associated with maladaptive thoughts, feelings, and behaviors.
2. Evidence-based treatments exist for somatic symptom and related disorders. Psychotherapy is the mainstay of treatment; early recognition and appropriate management may significantly improve prognosis.
3. Somatic symptom disorders are complex; an interdisciplinary team approach that integrates the neurological symptoms and the psychological distress may improve outcomes.

INTRODUCTION

Somatic symptom and related disorders are a group of psychiatric illnesses in which patients experience bodily symptoms along with associated abnormal thoughts, feelings, and behaviors that cause clinically significant distress and functional impairment. Patients with somatic symptom disorders initially present in medical or neurologic settings. These disorders may worsen medical and psychiatric morbidity among patients by increasing health care utilization and costs due to greater chronicity of symptoms and contribute to higher rates of disability. Patients with somatic symptom disorders can be among the most challenging for both psychiatric and nonpsychiatric clinicians. Some patients may have verified symptoms, but their emotional response is disproportionately distressing and maladaptive, and this adversely impacts physical function and well-being. Other patients may have notable anxiety or distress due to neurologic deficits, whereas there are no findings elicited during examination or on imaging. Evidence-based treatments exist for these illnesses, and timely recognition and appropriate management may significantly improve prognosis. Somatic symptom disorders are complex, and patients with these conditions often present to neurologists before they see or are referred to psychiatrists. Familiarity with somatic symptom disorders can be helpful to recognize when psychiatric consultation or referral is appropriate. This chapter provides an overview of the different types of somatic symptom disorders, epidemiology and pathobiology, management strategies, and outcome.

Somatic Symptom Disorders in *Diagnostic and Statistical Manual of Mental Disorders* (Fifth Edition)

The somatic symptom disorders are a group of disorders that have undergone significant diagnostic criteria revision in *Diagnostic and Statistical Manual of Mental Disorders* (Fifth Edition, *DSM-5*) (Table 156.1).

The diagnostic criteria for somatic symptom disorders (referred to as *somatoform disorders* in *Diagnostic and Statistical Manual of Mental Disorders* [Fourth Edition, *DSM-IV*]) gave rise to confusion about terminology and underdiagnosis by clinicians. The hallmark of somatoform disorders in *DSM-IV* was the absence of a medical explanation for somatic symptoms. This is problematic because conditions that are medically "unexplained" are not necessarily psychogenic in origin, that is, fibromyalgia and chronic fatigue syndrome are not considered psychiatric illnesses. The mere absence of a clear medical explanation for physical symptoms is not sufficient to make a psychiatric diagnosis; conversely, it is possible to have a documented medical condition and still have an abnormal psychological response to the physical symptoms. Patients with somatic symptom disorders *may or may not have a co-occurring and diagnosable medical condition*. The distinctive characteristic of these disorders has been shifted away from the somatic symptoms or their underlying etiology per se and focused on the maladaptive way in which the patient presents and interprets symptoms.

The terminology of somatic symptom disorders in *DSM-5* reduces the number of disorders and subcategories to minimize problematic overlap and diagnostic confusion. Somatic symptom disorders are defined on the basis of *positive* psychiatric symptoms rather than the *absence* of medical explanation for symptoms. The *DSM-5* criteria thus focus more on the psychological impact, particularly the distress caused by somatic symptoms and the patient's maladaptive response, and less on the definitive physiologic origin of the somatic symptoms. A *DSM-5* diagnosis of somatic symptom disorder does not require an exhaustive workup necessitating that the clinician rule-out any physiologically based medical condition. The notable

TABLE 156.1 *DSM-IV* Somatoform Disorders and *DSM-5* Somatic Symptom Disorders

DSM-IV Somatoform Disorders	*DSM-5* Somatic Symptom Disorders
Somatization disorder	Somatic symptom disorder
Hypochondriasis	Illness anxiety disorder
Conversion disorder	Conversion disorder (functional neurologic symptom disorder)
Pain disorder	Factitious disorder
Body dysmorphic disorder	Psychological factors affecting other medical conditions
Undifferentiated somatoform disorder	Other specified somatic symptom and related disorder
Somatoform disorder NOS	Unspecified somatic symptom and related disorder

Abbreviations: *DSM-IV, Diagnostic and Statistical Manual of Mental Disorders* (Fourth Edition); *DSM-5, Diagnostic and Statistical Manual of Mental Disorders* (Fifth Edition); NOS, not otherwise specified.

American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Washington, DC: American Psychiatric Association; 2013.

exceptions to this new rule are conversion disorder (functional neurologic symptom disorder) and pseudocyesis. *DSM-5* also eliminates the use of arbitrarily high-symptom requirements that were in the *DSM-IV* diagnostic criteria for somatoform disorders. A large body of research has shown that the relationship between somatic symptoms and psychopathology exists along a spectrum that was not adequately reflected by prior *DSM-IV* symptom count prerequisites.

The *DSM-IV* diagnosis of body dysmorphic disorder has been moved to the chapter on obsessive-compulsive disorder and related illnesses in *DSM-5* because there is a large body of research establishing pathophysiologic connections between obsessive-compulsive illness and body dysmorphia. Body dysmorphic disorder is thus no longer considered a somatic symptom disorder. This research has considerable treatment implications. Somatization disorder, hypochondriasis, pain disorder, and undifferentiated somatoform disorder (all diagnoses in *DSM-IV*) have been removed and incorporated into two central diagnoses in *DSM-5*: somatic symptom disorder and illness anxiety disorder. Factitious disorder is now considered a somatic symptom disorder in *DSM-5* because these patients often present with somatic symptoms. Psychological factors affecting other medical condition (PFAOMC) is now a psychiatric diagnosis in *DSM-5*. The diagnosis is quite prevalent in medical and surgical patients. The revised *DSM-5* criteria should reduce stigmatization of patients and improve diagnostic reliability across various medical disciplines.

Refer to the chapter on somatic symptom disorders in the *DSM-5* for more information.

SOMATIC SYMPTOM DISORDER

Introduction

Somatic symptom disorder is defined as an illness in which patients experience at least 6 months of one or more distressing somatic symptoms in addition to maladaptive thoughts, feelings, and behaviors related to these symptoms. This may include disproportionate or persistent thoughts about symptoms, an abnormally high level of anxiety about symptoms, and/or excessive time and energy devoted to the symptoms.

Somatic Symptom Disorder Case Example

A 60-year-old woman experiences rare palpitations and has been told she has a soft murmur of no hemodynamic significance. Her medical evaluation includes an echo stress test, numerous electrocardiograms, and a cardiac catheterization. She has been given the diagnosis of mitral valve prolapse, and told there is no need for treatment. She consistently makes appointments with her cardiologist driven by her fear of a "cardiac event" and severely limits her activities to not "stress her heart." The woman has somatic symptom disorder as her response to an insignificant medical finding is distressing and her maladaptive behavior of limiting her activity is not in keeping with the reality of her murmur.

Epidemiology

The prevalence of somatic symptom disorder is approximately 5% to 7% in the general adult population, approximately 15% in primary care, and over 50% in secondary care. The diagnosis of somatic symptom disorder may be applicable to more people, because diagnostic criteria in *DSM-5* emphasizes the adverse psychological burden of symptoms, and no longer requires that symptoms lack a medical explanation. Females report distressing somatic symptoms more frequently than males. Initial symptoms can begin at any age and usually appear by early adulthood.

Certain demographic factors are associated with a more severe clinical course, including female gender and older age. In elderly individuals, somatic symptom disorder is more likely to go unrecognized because of comorbid medical illness. The physical complaints of older patients may also be misattributed to "normal aging" or "understandable" concern.

Somatic symptom disorder occurs more frequently in individuals with lower educational/socioeconomic status, which is associated with more severe illness and worse outcome. Demographic factors that adversely impact the clinical course include unemployment, history of childhood physical or sexual abuse or other adversity, medical and psychiatric comorbidity, and external factors that reinforce the illness (eg, disability payments).

Pathobiology

Biologic, psychological, and social factors contribute to the development of somatic symptom disorder as is the case for most psychiatric illnesses. Biologic risk factors include genetic vulnerability to increased sensitivity to pain and other physical sensations. There is also an emerging literature to suggest a potential role for psychoneuroimmune mechanisms of somatic symptom amplification. Proinflammatory cytokines are known to be involved in the production of illness behavior. Chronic activation or sensitization of this system may result in nonspecific somatic symptoms and chronic pain. It has been hypothesized that immunologic mechanisms in the setting of infectious triggers may contribute to the development of somatic symptom disorders. Functional neuroimaging studies have demonstrated aberrant cortical and limbic activity in regions involved with emotion, self-referential processing, and motor planning; alterations in these regions may impact conscious processing and the experience of mild or chronically painful stimuli. Furthermore, beliefs and expectations also exert strong influence on how patients perceive symptoms, which may contribute to reports of functional abnormalities inconsistent with neuroanatomy and physiology.

Psychosocial risk factors for somatic symptom disorder include early childhood trauma such as physical, sexual, or emotional abuse and/or neglect. Social learning mechanisms such as the attention gained from physical illness or lack of reinforcement of nonsomatic (eg, emotional) expressions of distress may also contribute to the occurrence of somatic symptom disorder. Intrinsic temperamental factors may correlate with a higher risk of developing somatic symptom disorder, including alexithymia (difficulty identifying inner emotional states), and neuroticism (high levels of negative affect). Difficulties in communication—from intellectual, emotional, or social limitations—can predispose to bodily expression of distress.

Diagnosis

Patients with psychiatric illness often present with somatic symptoms, which are not diagnostic of somatic symptom disorder. The hallmark of somatic symptom disorder is that symptoms are prominent in the chief complaint; distressing; and

associated with maladaptive thoughts, feelings, and behaviors related to the symptoms. Patients with major depressive disorder may experience notable fatigue, whereas patients with anxiety disorders may experience tachycardia or abdominal pain. Usually, the cardinal feature of these other illnesses is a pronounced mood disturbance accompanied by numerous other physical and mental symptoms, whereas the distress in somatic symptom disorders emanates predominantly from the physical symptoms themselves. Mood and anxiety disorders frequently co-occur with somatic symptom disorders. Depressive disorders are common in patients with somatic symptom disorder, particularly in the elderly. Patients with somatic symptom disorder are at increased risk for developing secondary substance use disorders, with studies showing rates of opioid use disorders up to twice as high as seen in the general population.

Medical comorbidity is common among patients with somatic symptom disorder, which may complicate the diagnosis. Objectively corroborated problems should be judiciously investigated; however, unnecessary exhaustive diagnostic testing should be avoided because this may inadvertently reinforce the development of new somatic symptoms or even cause iatrogenic harm. Iatrogenic creation of symptoms may be subsequently mislabeled as psychogenic. Common complications of somatic symptom disorder include iatrogenic harm from invasive procedures or dependence on habit-forming substances such as opiates. Greater medical and psychiatric comorbidity is typically associated with greater severity of illness, degree of distress, and functional impairment.

Cultural factors are crucial when considering the diagnosis of somatic symptom disorder; many culture-bound syndromes present with prominent physical symptoms (eg, listlessness, diarrhea, and fever in Susto among the indigenous peoples of Latin America, or tremor and rapid heart rate in Taijin Kyofusho seen in Japan). Differences in medical care across cultures can also affect the presentation and course of somatic symptom disorders. The ways in which individuals recognize and respond to bodily sensations is influenced by numerous interacting factors that occur within a given social and cultural context, which effects the way in which the patient perceives illness and seeks medical attention.

Management

Somatic symptom disorder is difficult to treat, and the literature does not suggest a single superior treatment approach. An interdisciplinary "team" approach with collaboration between medical and mental health specialists is crucial to promote consistency, so the patient is less likely to feel dismissed or abandoned and to help minimize errors of diagnostic omission in either domain. It is recommended that one primary physician endeavor to form a stable relationship with the patient and arrange regular and reliable follow-up appointments on a predetermined scheduled basis.

When discussing the diagnosis of somatic symptom disorder with a patient, a thorough and empathic approach is most likely to put the patient at ease and facilitate successful psychiatric referral and follow-up. A discussion that somatic symptoms often have multifactorial causes may help patients understand that stress can generate physical symptoms without the patient's awareness. Clinicians should be mindful that some patients may be resistant to considering the relevance of psychological factors or may feel that the physician implies the problem is "in all in your head." Providing education about somatic symptom disorder and giving patients a list of psychiatric diagnostic criteria is helpful in legitimizing and validating their complaints by giving them a "genuine" diagnosis. Developing a relationship with the patient's family may also be helpful for understanding and managing the greater social context in which somatic symptoms tend to occur.

Various treatments are successful for somatic symptom disorders. The therapeutic focus shifts from "cure" toward symptom management. Psychotherapy is the mainstay of treatment for somatizing patients; such approaches include cognitive behavioral therapy (CBT) LEVEL 2[1,2] and psychodynamic psychotherapy LEVEL 2.[3] A meta-analysis of 15 randomized controlled trials of CBT for patients with somatoform disorders or medically unexplained symptoms showed that CBT significantly alleviated somatic symptoms, depressive symptoms, and improved physical functioning with efficacy maintained for up to 1 year of follow-up LEVEL 2.[4] Another meta-analysis found that psychotherapy, including forms other than CBT, can be effective for improving physical symptoms and functional impairment in patients with severe somatoform disorder and that improvements were maintained for 1 year after treatment LEVEL 2.[5] A limitation to existing evidence is that most trials evaluated patients using *DSM-IV* diagnostic criteria for somatoform disorder, and thus, further investigation is warranted using *DSM-5* diagnostic criteria for somatic symptom disorder.

Data suggests that pharmacotherapy can be helpful in the management of somatic symptom disorder. Serotonergic antidepressants are moderately effective in reducing intensity of functional somatic symptoms. Medications are helpful in treating the comorbid depressive and anxiety disorders. Agents commonly used for neuropathic pain such as mixed noradrenergic/serotonergic antidepressants, tricyclic antidepressants, and certain anticonvulsants may be helpful. The mechanism of action for these agents remains to be fully elucidated, but recent research findings suggest potential modulation of the psychoneuroimmune pathobiology described earlier discussion. In the case of somatic symptom disorder with predominant pain, use of addictive substances should be avoided.

Outcome

Early psychiatric intervention is likely to improve outcomes for patients with somatic symptom disorder; greater chronicity of undiagnosed somatization is correlated with worse outcomes and makes subsequent mental health treatment more challenging. A systematic review found that a majority of patients with medically unexplained symptoms, across all clinical settings, improved during follow-up, although 10% to 30% deteriorate. A possible explanation for improvement of symptoms may be partially due to regression to the mean because symptoms are at their worst when selecting patient during clinic visits. Without intervention, symptoms are likely to recur and may worsen in severity. When treating patients with somatic symptom disorder, consider the reinforcing role of secondary gain in maintaining symptoms. Although patients with somatic symptom clearly suffer, they may also obtain relief from certain societal, personal, and professional responsibilities as a result of their illness. Any successful treatment of somatic symptom disorder will seek as much as possible to eradicate these reinforcing agents and help reduce the possibility of further iatrogenic harm.

ILLNESS ANXIETY DISORDER

Introduction

Illness anxiety disorder was formerly termed *hypochondriasis* in *DSM-IV*. In *DSM-5*, illness anxiety disorder is characterized by a preoccupation with having or acquiring a serious medical illness that leads to clinically significant distress and dysfunction in social and/or occupational function, but bodily complaints and symptoms are absent or mild. The hallmark of illness anxiety disorder is distress and preoccupation related to the individual's *anxiety about the meaning or significance* of the somatic complaint rather than the actual symptoms. Patients with illness anxiety disorder have a high level of health anxiety that is disproportionate to their actual physical illness or risk of illness. They may engage in excessive health-related behaviors, including frequently checking their body or researching diseases on the Internet. Medical reassurance or negative diagnostic tests are unlikely to alleviate these patients' excessive concerns.

Illness Anxiety Disorder Case Example

A 35-year-old woman feels a lump in her breast. She has a strong family history of breast cancer and has a history of seeing doctors frequently for a variety of complaints that do not lead to a medical diagnosis. She requests an "emergency appointment" with a surgeon who tells her that she does not feel a mass. Imaging of the woman's breast shows no pathology. The woman continues to fear she has breast cancer, self-examines her breast repeatedly, and calls her gynecologist's office weekly with concerns that she might have breast cancer. The patient has no physical symptoms, that is, there is no lump in her breast. Her anxiety is unrelated to any pathology and is of an intensity to interfere with her life.

Epidemiology

Estimates of the prevalence of illness anxiety disorder are based on epidemiologic studies on the *DSM-IV* diagnosis of hypochondriasis. These community surveys and population-based samples demonstrate a 1- to 2-year prevalence of health anxiety and/or disease conviction ranging from 1.3% to 10%. In ambulatory medical populations, the 6-month/1-year prevalence rates are between 3% and 8%. Illness anxiety disorder is equally prevalent in males and females. A recent population-based study found 8.3% of those surveyed had high health anxiety alone, with no reported somatic symptom burden, which differentiates illness anxiety disorder from somatic symptom disorder.

Illness anxiety disorder is a chronic and often relapsing condition that typically begins in early to middle adulthood. In medical settings, no significant age differences have been found between those with low versus those with high levels of illness anxiety. In the general population, health-related anxiety increases with age, often focusing on cognitive deficits. The pathologic distress caused by health-related anxiety is distinct from whether or not there is a comorbid medical condition or cognitive impairment. Patients with health anxiety who develop disproportionate and dysfunctional distress about memory or cognitive function may have a family history or personal exposure to dementia, or due to health anxiety, interpret age-appropriate memory failure as pathologic. Particularly for older patients, it is important to differentiate between the irreversible progression of dementia and consider whether anxiety or functional memory impairment may be a contributing factor to the clinical presentation. Patients with functional memory problems have been reported as more likely to attend clinic alone and give extended, detailed descriptions of reported memory lapses; dementia patients often look to companions to help provide information and often have difficulty giving structured answers with confidence.

Pathobiology

There are biologic and psychosocial components to the development of illness anxiety disorder. A history of childhood abuse/neglect or serious childhood illness may be a potential risk factor for the development of illness anxiety disorder in adulthood (*DSM-5*). Major life stressors or illnesses are factors that may trigger the development of illness anxiety disorder.

Diagnosis

In order to make a diagnosis of illness anxiety disorder, the degree of worry or preoccupation must be *disproportionate* to the severity or significance of the physical symptom. The patient must have severe and continuous anxiety that causes significant distress for a minimum of 6 months. Even with a diagnosis of illness anxiety disorder, as with other somatic symptom disorders, it is important to evaluate the patient for the presence of an underlying or co-occurring medical or neurologic disease. Of course, anxiety related to health and well-being is a normal response to being diagnosed with a major medical illness.

Major mood and other anxiety disorders are other differential diagnostic considerations. Depressed patients can become preoccupied with concerns about their body and health. What distinguishes illness anxiety disorder from depressive and anxiety disorders is the patient's narrowed and persistent focus on health-related anxiety. Patients with illness anxiety disorder may develop depression; this may make it difficult to tease apart, which of the two is the primary psychiatric diagnosis. Patients with mood disorders and psychotic disorders may develop somatic delusions. Delusions are fixed, false beliefs that are held with a degree of conviction and intensity that is not typically seen in illness anxiety disorder. Patients with delusions believe their ideas are real in spite of evidence to the contrary (ie, distinguish between subjective internal experiences and the objective external world), whereas patients with illness anxiety disorder are usually able to accept the possibility that they may not be ill at all. Somatic delusions are often more bizarre or striking than the fears associated with illness anxiety disorder (eg, delusions of complete bodily decay). Patients who are psychotic and have somatic delusions typically have other symptoms of psychosis.

Illness anxiety disorder is a relatively new diagnosis, and therefore, exact rates of comorbidities are not yet known. Prior research on hypochondriasis suggests that comorbidity is high in these patients. As many as two-thirds of illness anxiety disorder, patients are likely to have at least one other major mental illness. Patients with significant illness anxiety are particularly likely to have comorbid depressive and anxiety disorders. Other common comorbid syndromes include somatic symptom disorder and personality disorders.

Management

The treatment of illness anxiety disorder has not been thoroughly researched. Evidence suggests that serotonergic antidepressants

may be effective for somatic symptom disorders characterized by predominant illness anxiety LEVEL 1.[6,7] Therapeutic dosages of selective serotonin reuptake inhibitors (SSRIs) may be higher than those for depressive and anxiety disorders. CBT may be a particularly effective form of psychotherapy LEVEL 1,[7,8] with the majority of patients responding with improved physical functioning quality of life, decreased pain, better function despite pain, and less sleep difficulty and maintaining these improvements at 12 months. Additional results found that the effect of both CBT and SSRI increased over a follow-up period of 18 months and were both effective at improving hypochondriacal complaints and comorbid symptoms of depression and anxiety LEVEL 1.[9]

A recent randomized controlled study showed systematic exposure and education about the role of avoidance as a maintaining factor in health anxiety produced clinically significant improvement in health anxiety among patients diagnosed with somatic symptom disorder or illness anxiety disorder, and this effect was observed when treatment was delivered through an internet-based platform with or without therapist support and also when provided in the form of a printed booklet. Further research is needed in this area, although these results suggest increased accessibility to treatment may help patients access effective therapeutic resources.

A randomized controlled trial in patients with *DSM-IV* hypochondriasis showed a greater response rate to a serotonergic antidepressant (fluoxetine) than to CBT and a small incremental advantage with joint treatment LEVEL 1.[10] Fluoxetine also significantly reduced anxiety and improved quality of life. Results from this trial are likely applicable to individuals with *DSM-5* diagnosis of illness anxiety disorder and somatic symptom disorder because anxiety and fears/beliefs related to illness remain prominent features of the condition. Other studies suggest greater remission and long-term maintenance of remission (over a mean of 8.6 y, range 4-16 y) in patients who continue treatment with SSRIs, as compared to patients who discontinued SSRIs.

Outcome

Patients referred early for psychiatric evaluation tend to have a better prognosis compared to those who receive only medical assessment and treatment. Psychiatric referral should be presented as a supplement, rather than an alternative to or replacement for ongoing medical care and evaluation. Continued treatment with SSRIs may maintain long-term remission and clinical improvement. Regularly scheduled, supportive treatment visits with a consistent primary care physician are helpful.

CONVERSION DISORDER (FUNCTIONAL NEUROLOGIC SYMPTOM DISORDER)

Introduction

Patients with conversion disorder or functional neurologic symptom disorder exhibit one or more symptoms of altered voluntary motor or sensory functions that cause significant distress or functional impairment. *DSM-5* specifies that *conversion disorder symptoms must be incompatible with recognized medical or neurologic conditions*. It may be difficult to determine clinically if a neurologic symptom is of so-called functional (no corresponding neurologic lesion (inconsistent with known neuroanatomy) or organic (with correlative neurologic findings) etiology, so the diagnosis should not be made simply because diagnostic tests are normal or because the symptom is "bizarre." Functional neurologic symptoms may be acute or chronic and may affect various or multiple sensory or motor modalities. The diagnosis of conversion disorder in *DSM-5* does *not* require that a psychological stressor precede the development of symptoms. This criterion was dropped because it is not always possible to immediately identify an antecedent stressor with the onset of functional neurologic symptoms. Nevertheless, it is important to make the diagnosis quickly in order to minimize morbidity or iatrogenic complications. The change in the diagnostic criteria does not imply that psychological factors are absent or not important for the patient and the symptoms.

In the most recent version of the International Classification of Diseases, ICD-10 updated in 2016, conversion and dissociative disorders are grouped together. A proposal for ICD-11 suggests moving conversion to the neurology section of ICD as functional neurologic disorder, which reflects a rationale similar to the changes in diagnostic criteria in *DSM-5*. Functional neurologic disorders and conversion symptoms should be described empirically based on observations and diagnosed based on positive features, with less emphasis on the potential psychological factors underlying the presentation.

The conventional psychodynamic model of conversion is that patients unconsciously transmute their psychic distress into physical symptoms. It can be difficult to definitively eliminate the possibility of conscious feigning when initially encountering a patient with conversion disorder. Therefore, the assessment of conscious versus unconscious production of symptoms is unreliable. Thus, the new diagnostic criteria for conversion disorder no longer require a definitive judgment that the symptoms are unconsciously produced.

Conversion Disorder Case Example

A 39-year-old woman is admitted to the hospital after sudden loss of function in her right arm. She is obese, is a cigarette smoker, and takes an oral contraceptive. She reports that she suddenly lost the ability to move or feel her arm during an argument with her teenage son whom she "felt like smacking." When hypnotized by the psychiatric consultant, she is able to lift her right arm while in the trance; however, the arm becomes limp when she is out of the trance state. To not shame or embarrass the patient, the psychiatrist tells the patient she will recover with physical therapy. She recommends psychotherapy to talk about her anger and to explore her relationship with her son.

Epidemiology

Methodologic differences in epidemiologic studies of conversion disorder have led to great variability in the reported rates of prevalence. Lifetime prevalence rates in the general population range from 11 in 100,000 to 500 in 100,000. In the general hospital setting and the outpatient neurologic setting, lifetime prevalence rates are 4% to 15%. Neurologic dysfunction of psychogenic origin occurs in 1% to 9% of neurologic diagnoses, and abnormal movements are among the most common symptoms; patients with psychogenic movement disorders are estimated to account for 2% to 3% of those in movement disorder clinics. Conversely, 10% to 15% of patients with psychogenic movement disorders also have associated organic neurologic disorders.

Conversion disorder usually presents in early adult life and is approximately 2 to 3 times more likely to occur in females. Conversion disorder is also more frequently seen in patients of lower socioeconomic status and those with relatively less education. As with the other somatic symptom disorders, psychiatric comorbidity is high, for example, depressive and anxiety disorders and posttraumatic stress disorder as well as personality disorders and impairment of psychosocial functioning. To date, there is no strong data showing any association between psychotic illnesses, such as bipolar disorder or schizophrenia, and conversion disorder or functional neurologic symptoms.

Functional neurologic disorders in children are similar to those in adults. Patients are often girls, age 10 to 14 years, presenting most commonly with motor loss and pain and lethargy. Two surveillance reports of conversion disorder in children reported approximately 70% of patients were female, and similar 12-month incidence of 3 to 4 per 100,000; incidence in children younger than 10 years of age was 0.26 to 0.8 per 100,000. Antecedent stressors were reported by approximately 60% to 80% of children with FND, most commonly bullying at school. Long-term data is limited to date.

Pathobiology

Functional neurologic symptoms are likely caused by a combination of biologic, psychological, and social factors; how these factors interact may vary in each patient. A growing evidence base, which includes neuroimaging studies, is improving the understanding of abnormal brain function and connectivity in patients with conversion or functional neurologic symptoms. Conversion disorder can present with almost any neurologic symptom, commonly abnormal movements or seizures, which appear to have a voluntary quality but are perceived by the patient as involuntary. Genetics and epigenetics, social and environmental influences, altered neural connectivity, abnormal cognitive processing, learning, and expectations may all play a role in the development of functional neurologic symptom disorder.

Biologically, an underlying personal or family history of organic neurologic disease is a risk factor for the development of functional neurologic symptoms. For example, patients with epilepsy are more likely to develop psychogenic nonepileptic seizures (PNESs) than the general population; the estimated comorbidity of PNES in epilepsy patients is approximately 10%. Maladaptive coping style and personality traits as well as difficulty identifying and expressing emotion (alexithymia) may predispose an individual to development of conversion symptoms.

Epigenetic changes that affect brain development and cognitive function may suggest a pathobiologic mechanism for the association between environmental factors, such as a history of abuse or trauma, and the development of conversion disorder. Studies comparing patients with PNES to healthy volunteers have found that PNES patients have higher basal cortisol levels, a marker of overall greater stress level that is unrelated to seizure frequency, physical activity, or acute psychological stress. Other studies comparing patients with PNES to patients with complex partial seizures have found that PNES patients have statistically significant pre-ictal heart rate increases and postictal heart rate reductions normalized to baseline and decreased resting vagal tone. Neuroimaging of PNES patients have shown alterations with and across sensorimotor, emotional regulation/processing, cognitive control, and multimodal integration brain systems (see **Table 156.2** which summarizes neuroimaging findings in patients with functional movement disorders).

Neuroimaging studies show different patterns of brain activation and deactivation in patients with conversion disorder as compared to patients who consciously feign symptoms. Although there is no commonly accepted theory about the functional neuroanatomy of conversion disorder, available evidence suggests that symptoms may represent a "functional unawareness syndrome" involving abnormal limbic-motor connectivity and networks involved in the processing of emotion and affect. Functional imaging studies have shown hypoactivity in the supplementary motor area (SMA, an area associated with action planning and selection) and abnormally strong connectivity between the SMA and amygdala, which is enhanced by emotional stimuli. This may suggest a mechanism to explain why patients with functional hyperkinetic movements may experience symptoms as involuntary, if SMA hypoactivity limits the ability to suppress an action. Other functional neuroimaging studies in patients with functional tremor have observed abnormal activation patterns in the cingulate cortex, ventromedial prefrontal cortex, precuneus cortex—brain regions involved with self-awareness and the affective and sensory component of memories. Increased regional cerebral blood flow has been observed in subcortical structures of patients with functional movement disorders, more so than in patients with essential tremor and organic dystonia.

Higher order cognitive processes that integrate and interpret sensory and motor stimuli are also implicated in functional disorders because perception and control of both movement and sensation are dynamically influenced by data from and interactions with the environment. A study examining sensory attenuation (ie, the effect that a touch generated by one's own movement is perceived with reduced intensity as compared to an identical touch by an externally generated force) found that patients with functional dystonia did not show the sensory attenuation seen in healthy controls and that the functional patients were also more accurate in perceiving forces caused by their own actions. The loss of sensory attenuation in patients with functional disorders may be related to an increased focus on somatic sensations, which combined with decreased inhibition of motor movements suggested by SMA hypoactivity, may increase the likelihood of perceiving actions as involuntary and reinforce these expectations in some patients.

Environmental factors such as childhood abuse/neglect and other stressful or traumatic life events can be associated with the development of conversion disorder. Although not all individuals who experience early adverse life events will develop conversion disorder, a controlled study found that patients with a "clinically definite" functional movement disorder reported significantly higher rates of childhood trauma and traumatic events as compared to healthy volunteers. Dissociation, a commonly seen psychological response to trauma, has also been described in patients with conversion disorder, particularly those with PNES. Researchers have hypothesized similar psychological processes underlying conversion and dissociative disorders despite the descriptive differences between the two conditions, likely with disturbances in higher level integrative cognitive functions affecting awareness, consciousness, identity, and memory. A history of trauma may increase vulnerability to later life stressors such as later trauma, illness, or injury. Functional movement disorders such as tremor and dystonia have been described, often developing with variable timing after a peripheral injury. There is a hypothesis suggesting that trauma or physical injury may unmask or exacerbate a preexisting vulnerability to develop abnormal movements, as reported in patients with genetic conditions such as mitochondrial disorders.

TABLE 156.2 Areas of Abnormal Activation Observed in Patients With Functional Movement Disorders[a]

Regions of Altered Activation	Observed Abnormalities in Patients With Somatization
Anterior insula	• Increased activity • Anterior insular cortex is associated with awareness of sensations and movement. • Inverse association between left anterior insular volume observed in patients with functional neurologic disorder and childhood abuse burden
Inferior frontal cortex	• Increased activation • Right inferior frontal cortex implicated in active inhibition of motor actions for speech
Ventromedial prefrontal cortex	• Increased activity • Implicated in internal self-representations and integrating memory and imagery with emotional components
Anterior cingulate cortex	• Increased activity • Observed with functional tremor and functional dystonia
Posterior cingulate cortex	• Increased activity • Seen in patients with functional disorders at rest or in response to emotional stimuli
Amygdala	• Increased activity • Increased and prolonged activation in response to positive and negative stimuli
Precuneus	• Increased activity • Hyperactivity observed with conversion disorders • Implicated in internal self-representations and integrating memory and imagery with sensory components
Cerebellum	• Increased activity • Higher regional cerebral blood flow • Enhanced activation in functional tremor compared to essential tremor
Right temporoparietal junction (rTPJ)	• Decreased activity • rTPJ detects discrepancies between internal motor intentions and actual motor effects.
Sensory and motor cortex	• Decreased activity
Dorsolateral prefrontal cortex (dlPFC)	• Decreased activity • dlPFC has functions in motor planning and regulation.
Presupplementary motor area (pre-SMA), supplementary motor area (SMA)	• Decreased activity, although increased activity seen to sad or fearful stimuli • SMA is involved in preparation and suppression of motor plans.
Abnormal Connectivity	**Possible Role in Pathogenesis of Somatization**
Hyperconnectivity between ventromedial prefrontal cortex and posterior cingulate cortex and precuneus	• Abnormal activation may affect internal self-representations and integration of memory with emotional or sensory components.
Hyperconnectivity between amygdala and SMA and PaGM	• Abnormally increased connectivity between limbic and motor regions in functional disorders • Periaqueductal gray matter, which is involved in freeze response to fear, has increased activity.
Decreased connectivity between rTPJ and several motor areas	• Implications for perceiving discrepancies between motor intentions and consequences
Decreased connectivity between dlPFC and SMA	• Abnormal top-down control by dlPFC may allow expression of previously learned patterned movements.

Abbreviation: PaGM, periaqueductal gray matter.
[a]Adapted from Baizabal-Carvallo J, Hallett M, Jankovic J. Pathogenesis and pathophysiology of functional (psychogenic) movement disorders. *Neurobiol Dis.* 2019;127:32-44 and Voon V, Cavanna AE, Coburn K, Sampson S, Reeve A, LaFrance WC Jr. Functional neuroanatomy and neurophysiology of functional neurological disorders (conversion disorder). *J Neuropsychiatry Clin Neurosci*. 2016;28(3):168-190.

Diagnosis

A diagnosis of conversion disorder should only be made following a thorough neurologic assessment, including detailed history and examination and relevant imaging or other studies. A thorough physical examination is essential to assess any neurologic symptom, no matter what the etiology. This conveys to patients that their physical presentation is being given due attention. The history may also provide information that suggests a functional component; patients may report a physical injury or illness as a trigger associated with the sudden onset of weakness, abnormal movements, or altered sensations (Table 156.3).

Conversion disorder and functional neurologic symptoms can be differentiated from organic illness by its incompatibility with known features of neurologic disease or inconsistency observed during physical examination. Functional abnormal movements may display characteristics that imply an element of voluntary control (eg, enhanced by attention, alleviated by distraction, entrainment of tremor); yet, the hallmark of functional symptoms is that patients perceive them as involuntary. These inconsistencies or incongruities are positive signs that point toward a diagnosis of conversion disorder; however, as with the other somatic symptom disorders, conversion disorder (or other apparent functional overlay) is not mutually exclusive with organic physical or neurologic illness. In fact, deficits due to neurologic disease are a risk factor for developing functional symptoms, as suggested by patients with both neurologic and functional diagnoses

TABLE 156.3 Factors Contributing to Functional Neurologic Disorders

Factors	Contribution to Functional Neurologic Disorders	Examples
Predisposing	Preexisting psychiatric conditions (mood or anxiety disorders, PTSD, excessive vigilance) or certain cognitive styles (eg, obsessive or rigid patterns of thinking) can make individuals more vulnerable to somatization. Trauma, abuse, or distressing experiences from the present, recent past, formative years, or childhood can be a risk for somatic symptom disorders. There may be mild genetic risk and other risk factors that are not yet known or well understood.	Excessive stress Emotional difficulties Heightened threat vigilance Cognitive style
Precipitating	Beliefs and expectations about health contribute to disordered sensorimotor processing to distort or amplify an unpleasant somatosensory experience. Misdirected or excessive attention, anxiety, and dissociation can facilitate aberrant processing or perception. Somatic symptoms offer a plausible "explanation" for confusing or conflicting experiences. Patients may be conscious of this, or their participation may be preconscious and out of their awareness.	Health beliefs Expectations Attentional processes Anxiety Dissociation
Perpetuating	Maladaptive behavioral responses can be reinforced by learning, social, and external factors. CNS plasticity and remodeling may contribute.	Behavioral responses Cognitive remodeling Social context External factors

Abbreviations: CNS, central nervous system; PTSD, posttraumatic stress disorder.

(eg, epilepsy and PNES, multiple sclerosis and functional weakness, idiopathic intracranial hypertension, and functional visual deficits). As noted by Pierre Janet, Charcot's assistant, "the fact that a system is psychological should not cause us to conclude that it is not at the same time anatomical. On the contrary, the one involves the other."

PNES, also called *psychogenic nonepileptic attacks* are among the most common functional neurologic disorder. The gold standard for diagnosis of PNES video-electroencephalogram (EEG) capture of episodes, with lack of ictal EEG discharges before, during, and after typical episodes of seizure-like activity. Evaluation with video-EEG is important because most patients with PNES are misdiagnosed with epilepsy and treated unnecessarily with antiepileptic medications, which provide no benefit to these patients and instead expose them to potential adverse effects. Subjective patient reports may also be helpful in differentiating between PNES and epilepsy, and some self-report questionnaires have been shown to accurately distinguish between PNES and epilepsy with sensitivity and specificity of 85%. Patients with PNES are more likely to describe their seizures as a "state or place" they enter passively, whereas patients with epilepsy describe their seizures as an external active force that independently acts on their body. Patients with PNES are more likely to emphasize their loss of consciousness as complete and absolute, even though some studies show a greater portion of PNES patients demonstrate some responsiveness or ability to follow simple commands during seizure events, as compared to patients with epilepsy. How patients experience and report PNES symptoms may aid in diagnosis and suggests aspects that may lead to better understanding of functional symptoms.

Conversion disorder should not be diagnosed simply based on the presence of psychiatric symptoms; depression and anxiety are common comorbidities with both organic and functional neurologic illness, whereas patients with psychotic illness are unlikely to have functional complaints. Depression and anxiety are often comorbid with functional neurologic symptoms. Assessing for psychiatric symptoms requires skillful tact because patients may feel extensive questioning to be dismissive of or detracting from what they perceive as the most bothersome aspect of their complaints. Patients often perceive low mood, anxiety, and stress as predictable responses to their somatosensory symptoms and may minimize low mood, anxiety, or stress, sometimes, intentionally, if they believe their problems are neurologic and perceive any discussion of psychiatric symptoms as distracting. In fact, some studies have shown that patients with functional disorders are less likely to attribute their symptoms to stress than patients with organic neurologic disease.

Overt evidence of deliberate feigning or exaggeration of symptoms should guide one away from a diagnosis of conversion disorder and more toward factitious disorder or malingering.

Management

Effective treatment of conversion disorder begins with empathic and positive communication of the diagnosis. It is generally best to avoid any comments that suggest to the patient that there is nothing "biologically" wrong in order to prevent embarrassment. It is helpful to inform, the patient that he or she is clearly suffering from real symptoms that are concerning and disruptive, but the expectation is that he or she will ultimately recover. The patient should be told that there is no need to be exposed to unnecessary medication or studies, which may be invasive and potentially cause harm, but that treatment focusing on managing the emotional issues and distress associated with the symptoms is very important for ultimate improvement. This type of phrasing can help engage the patient in a dialogue about any stress associated with the symptoms.

Any clinician treating patients with conversion disorder should be aware of the potential role of past trauma in this illness and should be sensitive to therapeutic implications in the management of a traumatized patient (particularly as it relates to forming a stable treatment alliance). Although the psychological conflict producing the symptoms may seem obvious to the physician, delicacy is required in presenting an interpretation of the proposed etiology to the patient. The most common "precipitants" are aggressive and sexual thoughts that are unacceptable to the patient; however, if the patient could adaptively cope with such thoughts then the symptoms would not be manifested.

Despite the illness burden of conversion disorder and the therapeutic challenges inherent in its management, there is a lack of empirical data on effective treatment strategies. The majority of evidence for the treatment of conversion disorder is in the form of uncontrolled case series and reports. In general, the cornerstone of management for conversion disorder has been

psychotherapy. There is little clinical evidence to support the use of pharmacotherapy in the absence of other comorbid psychiatric conditions such as depressive or anxiety disorders. Antiepileptic medication and surgical procedures have no efficacy for PNES and can cause significant harmful effects. Some success has been reported with antidepressants LEVEL 1,[11] mood stabilizers, and antipsychotics. Treatment with the antipsychotics is problematic given the potential for neuroleptic-induced movement disorder in patients who may already have psychogenic movement disorders.

Psychotherapy for conversion disorder should aim to help the individual develop more adaptive coping strategies to deal with emotional conflicts and more effective ways of communicating distress. CBT is one such therapeutic modality LEVEL 1.[12] Psychoanalytic and psychodynamic approaches to conversion can also be quite effective LEVEL 1.[13]

In addition to psychotherapy, there are studies of small sample sizes with preliminary findings suggesting possible efficacy for hypnosis LEVEL 1,[14,15] behavioral therapy and rehabilitation, physical therapy, and paradoxical intention. Incorporating hypnosis as an adjunctive technique has support from current theories about the role of suggestion and expectation in the development of functional symptoms. These treatments can be potentially "face-saving" and more readily acceptable for the patient, as they are based on a physical model of recovery, and may be particularly helpful for patients who have difficulty engaging in psychotherapy.

Outcome

There is great variation in the degree of symptom severity among patients with conversion disorder. Although conversion symptoms can be short-lived, it is not unusual for symptoms to recur in the same individual; 1-year relapse rates can be as high as 20% to 25%. Good prognostic factors include acute onset and short duration of symptoms, presence of an identifiable stressor at the onset of illness, short interval between onset and referral to treatment, higher intelligence, and willingness to accept a psychological component to the illness. Underlying personality disorder is a poor prognostic indicator, as is comorbid somatic symptom disorder. The more long-standing the conversion symptoms, the more difficult it becomes to treat the disorder. This may be because of the accumulation of associated benefits over time (eg, secondary gain). Comorbid psychiatric and medical illness is also associated with worse outcome.

FACTITIOUS DISORDER

Introduction

Unlike the other somatic symptom disorders, factitious disorder involves *intentional falsification of* physical and/or psychological symptoms, or induction of injury or disease. The individual is aware of the deception and presents him or herself as ill, injured, or impaired. A subtype of factitious disorder involves the presentation of someone else close to the patient as ill, injured, or impaired. This was previously called *factitious disorder by proxy* in *DSM-IV* and is now referred to in *DSM-5* as *factitious disorder imposed on another*. Patients with factitious disorder may present with single or recurrent episodes. Münchhausen syndrome is a particularly chronic and intractable form of factitious disorder.

Unlike the malingering patient, those with factitious disorder exhibit deceptive behavior *in the absence of any obvious external reward*. The traditional model of this illness rests on the idea that patients seek secondary gain via assumption of the sick role; however, *DSM-5* does not specifically list this as a diagnostic criterion because it is often not possible to reliably infer this early on in the disease course. The deceptive behavior is not always about medical symptoms. Factitious mourning has been reported in which individuals relate a history of traumatic loss of a loved one.

Common clinical characteristics often include a history of numerous prior medical evaluations and treatments, particularly hospitalizations, surgeries, and other invasive procedures. Other features that suggest the diagnosis include a dramatic or inconsistent history that is vague or variable in its detail, inexplicable laboratory results, inconsistent physical examination findings, use of highly medicalized jargon, minimization of the presence of scars from prior invasive procedures, or confabulation of details when attempts are made to corroborate history. Patients may also demonstrate remission of neurologic deficits when they believe no one is observing. The classic example of a patient with factitious disorder is someone who migrates to different treatment settings in order to avoid discovery of the psychopathology.

Factitious Disorder Case Example

A 48-year-old woman is admitted for evaluation of an inoperable brain tumor. Neuroimaging results from extensive prior hospitalization records reveal no evidence of central nervous system pathology. When confronted by the medical team, the patient reveals that she falsified her medical records. She also disclosed that she planned to commit suicide and wanted her family to think she had an incurable cancer and would understand it when she took her life.

Epidemiology

Because of the level of deception in patients with factitious disorder, exact estimates of prevalence are unknown. In the general hospital setting, approximately 1% of individuals meet criteria for the disorder, but rates may be higher in specialized treatment settings. Factitious disorder is likely significantly underdiagnosed by physicians who are reluctant to confront deceptive patients and also due to the fact that patients rarely participate in psychiatric evaluation and treatment, and many often flee or abruptly elope from care when confronted about their deception. The typical course of factitious disorder is recurrent, intermittent episodes that last over the course of the lifespan. Patients usually present during adulthood, often before age 30 years, although there may be earlier evidence of unexpectedly numerous illnesses and procedures during childhood. Factitious disorder is more common in women, but its course is often more severe and refractory in men. Medical child abuse, a form of factitious disorder imposed on another, has an estimated prevalence ranging from 1% to 13% in studies conducted in specialist settings.

Pathobiology

Risk factors for factitious disorder include a history of childhood abuse, disturbed parental relationships/emotional deprivation, early life illness or extended hospitalizations, and exposure to or employment in the medical setting. There are

several psychodynamic as well as cognitive, social learning, and behavioral theories that have been posited for the development of factitious disorder. Behaviors leading to factitious disorder may begin at a young age when an individual experiences envy from observing the attention received by someone else who is ill or receives positive attention during their own illness or loss and then associates the pleasant experience of attention with the role of being sick. An interesting study of an online community of self-reported sufferers of factitious disorder revealed that members claimed to be aware of their motivations, were upset by their behavior and wanted to recover, and were deterred by fear from seeking treatment. Neurobiologic findings of functional imaging studies have been inconsistent.

Although little is known definitively about the motivations of patients with factitious disorder, their behavior may be a maladaptive attempt to seek care for perceived or genuine distress. Patients with factitious disorder have variable awareness of their deception, although it has been reported by observers and patients that there is often a compulsive element to the deceptive behavior, such that patients are conflicted between not wanting to engage in deceptive behavior and the simultaneous urge to occupy the sick role. Similarities between addiction and factitious disorder have been suggested, particularly the reinforcement from the emotional reward of attention and sympathy gained from occupying the sick role.

Diagnosis

A presentation inconsistent with the known natural history of a medical condition, and investigative studies that are normal or inconclusive, often lead to the diagnosis of factitious disorder. Other factors that may suggest this diagnosis include prior extensive health care use (often at multiple locations) or with symptoms predominantly manifesting when the patient is not observed. Corroborating information and past treatment records are difficult to obtain, and the patient may be inconsistent, evasive, or confrontational when asked for additional details. Patients with factitious disorder have been reported to display an unusual degree medical knowledge or use of medical terminology, appear eager for medical procedures and surgical interventions while resisting psychiatric involvement.

The major differential diagnostic consideration in factitious disorder is malingering (which is not a psychiatric diagnosis). Malingering patients fabricate medical problems to gain clear external rewards (eg, disability benefits, evading legal or military obligations), whereas patients with factitious disorder also intentionally fabricate medical needs, although not for obvious tangible gains. Most often, patients with factitious disorder are motivated by seeking the attention they receive while occupying the sick role. Malingering and factitious disorder patients may engage in a similar array of behavior when they intentionally falsify information, which ranges from exaggerating symptoms, deliberately concealment of information that would account for their presentation, feigning, inventing symptoms, misattributing cause, or self-inflicting illness or injury. Patients may have features or elements of both conditions, that is, a patient may be subconsciously motivated complain of pain while enjoying access to opiates. Many clinicians have difficulty differentiating between the somatic symptoms of factitious disorder and those of conversion disorder. The hallmark of factitious disorder is *deliberate* deception or fabrication of symptoms. In conversion disorder, patients do not intentionally produce symptoms.

Patients with factitious disorder who injure themselves do so specifically in order to assume the sick role. Factitious disorder often presents following a hospitalization for a medical condition or mental disorder. In factitious disorder imposed on another, it is following the child or dependent party's hospitalization. A systematic review of 796 published cases of medical child abuse found that nearly all abusers were female (97.6%), almost all were the victim's mother (95.6%), most were married (75.8%), and many reported to have health care–related professions (45.6%). From upon reviewed cases, the most common psychiatric diagnoses were factitious disorder imposed on self (30.9%), personality disorder (18.6%), and depression (14.2%). Seizures are reportedly the most common presentation of fabricated or induced illness in children (published cases include factitious reports by the caregiver and children administered drugs that cause seizures); examination of medical records for the child's caretaker (usually the mother) frequently include reports of nonepileptic seizures.

Patients with factitious disorder are not attempting to kill themselves or to obtain affective or emotional release from the self-injury. This distinguishes their self-harming behavior from those of patients with mood or personality disorders. Patients with factitious disorder may have comorbid mood and personality disorders and have frequent comorbid substance use disorders.

Management

Factitious disorder is one of the most difficult psychiatric illnesses to treat. Early identification of factitious disorder is important to limit unnecessary health care interventions, prevent potential iatrogenic harm to the patient, and manage the psychological impact on providers. A review of 455 published cases of factitious disorder found that 59% of patients self-induced injury or illness, whereas only 19% simulated and 22% falsely reported a medical problem. In this case series review, 14% of patients reported current suicidal ideation or past suicide attempt. Although patients with factitious disorder may appear medically knowledgeable, and often, use this to induce the circumstances for their presentation, their capacity to appreciate the harmful consequences of their behavior is impaired and their actions can lead to serious, permanent damage or potentially death. Whatever the motivation, patients with factitious disorder should be considered to be at high risk for self-harm and managed accordingly.

If a diagnosis of factitious disorder is suspected, it is often helpful to confer with hospital administrative and legal services. A strategy of supportive confrontation has been recommended by some experts, which always involves more than one member of staff, and emphasizes the patient is sick and in need of help. Other suggestions include face-saving options that might allow patients to claim to others that they "recovered" without revealing they fabricated their symptoms.

Not surprisingly, clinicians often have strong negative emotional reactions to patients who falsify symptoms. Care providers may feel exploited, humiliated, or angered. Clinicians report feeling guilty or ashamed for not recognizing false information sooner and concern that their emotional reaction might affect care for that patient or others. It is important to remember when treating the patient with factitious disorder that he or she is in fact quite ill but not in the way he or she presents.

An additional therapeutic challenge is the fact that patients often abruptly flee from care once they are confronted about the

false nature of their symptoms; other responses include denial or threats of litigation. Patients with factitious disorder are reluctant to seek treatment, and although precise reasons for this are not fully known, many of the perceived barriers may be fears similar to those faced by people reluctant to seek help for addiction including fear of disclosure, abandonment and rejection, losing a coping mechanism, and the difficulties of overcoming defense mechanisms.

Outcome

There is a dearth of comparative literature examining the efficacy of various treatment approaches. In general, it is recommended that treatment be collaborative, involving interdisciplinary team meetings and communication among providers to coordinate efforts and manage negative emotions. Psychodynamic and behavioral approaches have been used to treat the disorder. Pharmacotherapy has a role in treating specific comorbid symptoms, such as mood or psychotic disorders, if present. The ultimate goal is to redirect the patient to seek psychiatric care in an appropriate setting and support the patient in developing more adaptive behaviors.

PSYCHOLOGICAL FACTORS AFFECTING OTHER MEDICAL CONDITIONS

Introduction

Psychological or behavioral factors that adversely affect other medical conditions (PFAOMC) are very common. This diagnosis is included in the group of somatic symptom disorders because of its usual appearance in primary care and other medical settings. The essential feature of PFAOMC is clinically significant psychological or behavior factors that adversely affect a medical condition by increasing the risk for suffering, disability, or death. Psychological or behavioral symptoms may include psychological distress, patterns of interpersonal interaction, coping styles, and maladaptive coping strategies such as denial or poor adherence. A common example is denial of the significance of physical symptoms, which may in turn lead to delayed medical intervention. Clinically significant psychological factors can affect any medical condition, including those with clear pathophysiology (eg, epilepsy), functional syndromes (eg, fibromyalgia, chronic fatigue syndrome), or idiopathic medical symptoms (eg, pain, fatigue, dizziness).

There may be a temporal relationship between psychological factors and development or exacerbation of a medical condition, as in the example of a depressed patient with diabetes mellitus who neglects glucose control. Psychological factors may also interfere with treatment of a medical condition. Patients with a history of trauma may be particularly sensitive to certain invasive procedures and become resistant to medical workups. Psychological factors can constitute additional health risks or adversely influence underlying pathobiology. A hypoxic patient with pulmonary disease who subsequently develops anxiety will experience vasoconstriction secondary to release of catecholamines, resulting in further reduction of oxygen delivery to tissues and a positive feedback loop contributing to exacerbation of both hypoxia and anxiety.

PFAOMC Case Example

A patient with a well-documented history of epilepsy is brought to the emergency department in *status epilepticus*. When he recovers, he states that he has taken all of his medications as prescribed; however, serum levels of the anticonvulsants are not detectable. When confronted with this information, he admits that it is not "strong" to take medication and he stopped his medication. During his meeting with the psychiatric consultant, he elaborates further that he stopped taking medications as they were constant reminders of his illness and that having to rely on medication made him feel "weak." The psychiatrist notes that even the "best of the best" get help such as progolfers having a swing coach, something with which the patient could identify. Over the next week in the hospital, the patient and psychiatrist explored strategies for seeing the medications as allowing the patient to really be himself, not someone with seizures.

Epidemiology

The exact prevalence of PFAOMC is unknown; however, private insurance billing data from the United States indicates that this diagnosis is made more commonly than somatic symptom disorder. Denial of medical illness is not currently a diagnosable disorder in *DSM-5* but is commonly seen in clinical settings.

Pathobiology

Psychological factors may impact a medical illness at any point during the life cycle. Older individuals may be at greater risk for their own health to be adversely impacted by the stress associated with providing care for an ill partner. Clinicians should be mindful that greater age, greater prevalence and severity of comorbidities, and social factors can combine to increase the risk for elderly patients to develop psychological factors that then adversely affect other medical conditions.

Diagnosis

By definition, the diagnosis of PFAOMC necessitates the presence of a comorbid medical illness along with a psychological symptom or behavior. The hallmark of PFAOMC is the directionality of psychological factors adversely affecting underlying medical or neurologic disease. Conversely, when psychiatric symptoms develop predominantly in response to the stressor of medical illness, a diagnosis of adjustment disorder is more appropriate. In actual clinical practice, psychological syndromes often co-occur with medical illness in a mutually exacerbating fashion, making it difficult to determine the exact direction of causality. If the symptoms leading to aggravation of medical illness are best explained by another major mental illness such as major depressive disorder, then it is this condition that should be noted rather than PFAOMC.

Management

These patients should be managed by both their neurologist and a psychiatrist with full acknowledgement that the patient has a neurologic illness as well as clinically significant psychological distress that impacts the illness. Some patients will benefit from education about the interaction between stress and the body. The use of relaxation techniques, hypnosis, breath training, and meditation are all useful to engage the patient in taking control over what feels out of control.

Outcome

The outcome in these cases depends on a compassionate approach to the exacerbation of the neurologic symptoms.

CONCLUSIONS

Somatic symptom disorders are a complex group of psychiatric illnesses that cause much suffering for the patient and are frequently frustrating for the clinician as well. This chapter has reviewed major recent findings on epidemiology and what is known about the pathobiology specific to each of the somatic symptom disorders. Fortunately, a variety of evidence-based therapeutic modalities are available for some of these disabling disorders. Management should focus on understanding and treating dysfunctional thoughts, feelings, and behaviors related to the somatic symptoms, as opposed to attempting to complete eliminating the symptoms themselves. Invasive workups should be initiated with caution. Early recognition and appropriate referral by general medical and neurologic practitioners remain the initial crucial step in facilitating treatment and may significantly improve outcomes. Neurologic follow-up is important to prevent feelings of abandonment and ensure that relevant medical or neurologic illness is not missed.

Neurologic Rehabilitation 157

Joel Stein and Heidi Schambra

KEY POINTS

1. Rehabilitation is a key component of management for many neurologic disorders, such as stroke, brain injury, spinal cord injury, multiple sclerosis, and brain tumors.
2. Central nervous system plasticity underlies recovery of neurologic impairments and may be facilitated through goal-directed activity.
3. Compensatory approaches are often needed to restore maximum functional independence when neurologic recovery proves insufficient alone.
4. Rehabilitation commonly requires a team approach. Physician leadership and advocacy is important to coordinate care and make certain patients receive appropriate rehabilitation services.

INTRODUCTION

Neurologic disorders commonly cause impairments that impede intellectual and physical activities. Neurologists, physiatrists, and other physicians play an important dual role: (1) prescribing and monitoring rehabilitation therapies to maximize functional recovery and (2) optimizing patient health to maximize engagement in these therapies. The type and timing of these therapies substantially contribute to the quality of life for patient and family. However, access to rehabilitation services can vary significantly, and many individuals with acute and chronic neurologic conditions do not receive adequate rehabilitation therapy. With proper training and equipment, these individuals may improve in their independence, their access to the community, and the ease with which caregivers assist them. The medical and neurologic management of patients with neurologic injury begins in the acute setting and continues throughout the course of care, through varied institutional and home settings. Understanding the scope of neurorehabilitation is thus essential in the management continuum of acute to chronic neurologic disorders.

The World Health Organization's *International Classification of Functioning, Disability and Health* defines limitations caused by disease in three broad categories: bodily functions, activity participation, and societal participation. These definitions provide a framework for understanding the impact of disease on personal independence and integration into society and can furthermore help identify patients who may benefit from rehabilitation. The planning and prescription of a rehabilitation program for a neurologically impaired individual requires characterization of the neurologic disorder in terms of natural history, localization, and extent of nervous system involvement; determination of cognitive and physical impairments and their resulting activity limitations; and understanding these disabilities in the context of the patient's physical and social environment. Combining this information with knowledge of available resources for postacute care, the type and intensity of rehabilitation therapies can be planned.

Impairments caused by neurologic disease or injury frequently affect an individual's ability to perform functions, such as activities of daily living (ADLs) and instrumental ADLs. The ADLs include the basic activities an individual performs daily, including feeding, grooming, dressing, toileting, bathing, and mobility. Instrumental activities of daily living are activities beyond basic self-care that allow a patient to participate in the home and community, such as meal preparation, housekeeping, laundry, shopping, using a telephone/technology, driving a car/using transportation, and money management.

A broad range of neurologic disorders may benefit from rehabilitation interventions. These include acute neurologic disorders, such as stroke, traumatic brain injury, and spinal cord injury; fluctuating disorders, such as multiple sclerosis and neurooncology; and progressive disorders, such as Parkinson disease, neuropathies, amyotrophic lateral sclerosis, and others. For individuals with acute neurologic events, a postacute period of rehabilitation, either in an inpatient rehabilitation facility (IRF) or hospital or in a skilled nursing facility (SNF), is commonly necessary and can be an important component of the patient's overall recovery. For chronic or progressive conditions, inpatient rehabilitation is unusual, and most care is provided in an outpatient setting. Limitations in the duration and amount of rehabilitation services covered by insurance are common and may result in suboptimal care for individuals whose needs exceed the covered services. Novel technologies, such as telemedicine, wearable robotics, and others, may provide an opportunity to move more rehabilitation into the home and serve as extenders of rehabilitation therapies at lower cost.

COMPENSATION AND RECOVERY

Two principal approaches are used in neurorehabilitation programs: compensating for impairment and reducing impairment by enhancing neurologic recovery. *Compensation* teaches techniques that leverage preserved neurologic function to adapt to and manage neurologic impairment. Often, equipment of various types (eg, a brace, walker, tablet computer) is a component of a compensatory strategy. For example, a person with a paralyzed arm can be trained in one-handed techniques using the nonparetic arm, a patient unable to walk can learn to use a cane and a leg

brace, or a patient with severe dysarthria can communicate with a tablet computer using speech synthesis. Although compensation yields faster results and improves functional independence by reducing disability at activity level, it does little to diminish the original neurologic impairment. Troublingly, rodent models suggest that training compensation after stroke (eg, using the nonparetic limb to grasp a food pellet) impedes the beneficial effects of training to reduce impairment in the paretic limb.

Enhancing neurologic *recovery* entails the augmentation of endogenous neuroplastic processes and the facilitation of functional return. A mainstay of this approach is the practice of functional, task-specific activities. For example, a patient can practice reaching and grasping with a paretic arm to improve motor control, a patient with gait dysfunction can practice locomotion, or a patient with visuospatial neglect can practice shifting attention to the neglected space. This approach requires intensive training for weeks to months and contributes to the biologic restoration of function. Other strategies to enhance neurologic recovery include noninvasive brain stimulation with repetitive transcranial magnetic stimulation or transcranial electrical stimulation, neuropharmacology, peripheral and vagal nerve stimulation, and potentially stem cells and/or growth factors. Because these strategies are often insufficient to restore neurologic function, many patients require compensatory approaches to achieve adequate function in daily life.

Some combination of compensatory and recovery training is commonly used in neurorehabilitation programs. However, given the short lengths of stay in postacute rehabilitation facilities and the cost-benefit considerations of compensatory and impairment training, a personalized selection of rehabilitation approaches is warranted. Tailoring the rehabilitative approach based on recovery potential is an area of current clinical research. Knowing a patient's potential would enable clinicians to set realistic rehabilitation goals and could steer the rehabilitation team toward the most appropriate therapeutic approach. For example, a recently developed algorithm uses a patient's early motor function and corticospinal tract integrity (as determined by transcranial magnetic stimulation) to both predict motor recovery and guide rehabilitation approaches, including the incorporation of compensatory strategies.

In addition to these strategies to promote recovery of motor dysfunction, a variety of novel methods have been developed to facilitate motor training. These include robot-aided rehabilitation, which has been found to be modestly effective compared with conventional clinical rehabilitation. However, superiority has not been convincingly demonstrated relative to dose-matched upper limb exercise or gait training for stroke patients. Virtual reality, mirror therapy, and mental imagery practice are also under study as methods to either augment conventional movement training or to enhance engagement in treatment.

Exercises to increase the strength of muscle groups are also commonly used for stroke survivors and individuals with brain injuries. Of note, cortical map reorganization in animal models does not result from resistance training, and there is insufficient evidence from clinical trials to support the use of resistance training to aid in recovery LEVEL 3.[1]

Most patients who have marked neurologic injury, particularly those with stroke, are deconditioned and have limited exercise capacity and aerobic reserve. Rehabilitation therapy with mobilization and exercise helps to increase general conditioning and tolerance for exercise. In animal models, aerobic exercise increases production of brain-derived neurotrophic factor, which supports synaptogenesis and synapse stabilization. A meta-analysis of human stroke rehabilitation trials showed improvement in disability with aerobic cardiorespiratory training, largely attributed to improved gait and balance metrics LEVEL 1.[1]

For some conditions, such as complete spinal cord injury or amyotrophic lateral sclerosis, recovery may not a realistic goal. Novel compensatory devices may provide a path toward restored function. For individuals with paraplegia, exoskeletal robotic systems for the lower limbs allow resumption of walking in a limited fashion for some individuals. Neuroprostheses remain experimental at present but hold the potential to bypass damaged parts of the nervous system to restore a portion of lost abilities. Some of these use electroencephalography or other noninvasive systems, whereas others use cortical electrodes and computational systems to detect and decode motor intent and to convey commands to a patient's arm, a robotic arm, or a computer or other device.

NEUROPLASTICITY AND RECOVERY

Following focal injury, the central nervous system (CNS) undergoes long-lasting structural and functional changes. Neuroplasticity is upregulated after injury, and this enhanced state can be engaged to maximize the activity-dependent plasticity that results from rehabilitation training. Injury-induced plasticity after CNS injury and activity-dependent plasticity share many common mechanisms and substrates. Importantly, it is the interaction of both that produces maximal recovery gains.

Injury-Induced Plasticity

Injury to the CNS activates biologic recovery processes. Elucidating the mechanisms of neurorecovery is a rapidly evolving field. Animal models of CNS injury, particularly ischemic stroke, have helped build our understanding of the complex molecular and cellular aspects of recovery in the brain and spinal cord. Rapid, significant changes in gene expression and protein production occur after ischemic injury and may help or hinder plasticity in perilesional and remote interconnected areas.

At the cellular level, processes that promote plasticity include neurogenesis and angiogenesis, axonal sprouting, dendritic arborization, synaptogenesis and silent synapse unmasking, changes in synaptic strength, and changes in glutamatergic and GABAergic tone. Processes that limit plasticity include excitotoxicity, delayed neuronal death, edema, inflammation, expression of growth inhibitors, and glial scar formation. Free radical formation, astrocyte activation, and slow synchronized depolarizations have both helpful and harmful effects. Importantly, these processes peak and fade within the first weeks to early months after injury, underscoring the limited time window for pairing with rehabilitation training.

Studies targeting these plasticity modifiers, either by upregulating or downregulating their effects, are actively underway. For example, in animal models, selective serotonin reuptake inhibitors increase expression of brain-derived neurotrophic factor and synaptogenesis and prolong the window of recovery. Although some preliminary evidence in humans suggested fluoxetine might enhance motor recovery, recent larger clinical trials have failed to confirm effects on disability.

In traumatic brain injury, amantadine has been shown to accelerate recovery but not to alter ultimate outcome LEVEL 2.[2]

Other medications continue to be evaluated as potential recovery agents in preclinical and clinical trials, but none are currently considered standard care.

Activity-Dependent Plasticity

Using training to capitalize on neuroplasticity after brain injury is a key objective of neurorehabilitation. The optimal type, timing, and dose of training required to maximize activity-dependent plasticity after CNS injury is an active area of basic and clinical research. Some direction about best practices can be gleaned from animal stroke studies in the motor system. One clear principle that has emerged from animal models is that injury-induced plasticity needs to interact with paretic limb training in order to promote recovery. For example, in a nonhuman primate model of stroke, untrained animals achieved only half of the behavioral function of their trained counterparts, even when given twice as long to recover—in other words, injury-induced plasticity alone is insufficient to restore function. In a rodent model of stroke, trained rats show both increased perilesional synapse formation and improved behavioral function compared to their untrained counterparts. These results suggest that physical training, eliciting activity-dependent plasticity in its own right, engages with injury-induced plasticity to produce better functional gains.

How early to begin therapy is a point of debate, given concerns about glutamate excitotoxicity after CNS injury. In rodent models of stroke, paretic limb training started 5 days after stroke results in greater functional gains than the same amount of training started 30 days after stroke. However, there is some concern that too much therapy very early after injury may have adverse consequences. A large multicenter pragmatic randomized controlled trial (RCT) of early mobilization after stroke, the a very early rehabilitation trial after stroke (AVERT) trial, found that more aggressive mobilization within the first 24 hours poststroke resulted in poorer long-term outcomes LEVEL 1.[3] Even outside of the 24-hour window poststroke, optimal dosing and timing of therapy remains unclear, as demonstrated in a randomized, single-blind phase II trial that found that a higher dose of constraint-induced movement therapy initiated within 2 weeks poststroke resulted in less motor improvement.

The dose of therapy is also an issue of exploration. From animal and human motor learning studies, it is clear that high doses of repetitive, goal-directed practice are required for long-term skill gains. Yet, an RCT of varying levels of upper limb task-oriented training poststroke failed to demonstrate any advantage for higher doses LEVEL 1,[4] and an RCT of high-dose training delivered 6 months or more poststroke showed little effect on function LEVEL 1.[5] Overall, these studies demonstrate that we do not yet know the optimal dose, timing, or duration of rehabilitation after stroke or other neurologic injuries.

LEVELS OF CARE

Rehabilitation services are provided in a variety of settings and at varied levels of intensity and duration. Postacute care can occur in IRFs, in SNFs, from home health agencies, or at outpatient facilities. At IRFs, patients receive 3 hours of therapy 5 to 7 days per week for usually less than 1 month. There is daily physician (typically physiatrist or neurologist) oversight. At SNFs, patients receive 0.5 to 2 hours of therapy 5 to 6 days per week for usually less than 2 months. There is weekly to monthly physician oversight, usually by a general practitioner, internist, or geriatrician. In outpatient therapy, be it in-home or at a facility, patients receive 0.5 to 1 hour of therapy 2 to 3 times per week, durations average 1 month, and physician oversight is typically very limited.

In an IRF, the most common neurologic diagnoses are stroke, traumatic and nontraumatic brain injuries, and spinal cord injury; also seen are brain neoplasms, multiple sclerosis, Parkinson disease, and peripheral neuropathies (particularly critical illness neuromyopathy and acute inflammatory polyneuropathy). For patients hospitalized with acute neurologic injury, functional outcome is improved by an experienced, coordinated interdisciplinary team providing a comprehensive rehabilitation program. Stroke patients who receive rehabilitation therapies on a stroke rehabilitation unit have better functional outcomes and shorter hospital stays than those treated on a general neurology ward, and benefits persist over time. Similarly, stroke patients admitted to hospital-based intensive rehabilitation programs have better functional recovery and are more likely to return home than those treated in a low-intensity rehabilitation program at an SNF. For these reasons, the American Heart Association's Stroke Rehabilitation Guidelines recommend that "stroke survivors who qualify for and have access to IRF care receive treatment in an IRF in preference to a SNF."

Multiple considerations go into determining the best placement for the medically stable neurologic patient. For admission to an IRF, the patient must have impairments that necessitate at least two therapy types (see the following text), must tolerate at least 3 hours of therapy daily, and must have 24-hour medical and nursing needs. Placement at an SNF typically occurs when the patient is unable to tolerate a high intensity of rehabilitation or has low capacity for functional improvement and has reduced medical and nursing needs. Outpatient therapy is appropriate for patients with mild and limited deficits or follows a course of inpatient rehabilitation to extend functional training at home or in the community. Interestingly, availability of postacute care has been demonstrated to be an important predictor of its use. Nonclinical factors that strongly influence placement include availability, convenience, distance to provider, demographic factors (age, race, and marital status), insurance status, local practice patterns, and characteristics of the discharging hospital (size, ownership, status as a teaching hospital, etc).

THE DISCIPLINES

A comprehensive inpatient neurorehabilitation program requires an interdisciplinary team composed of the physician, physical therapist, rehabilitation nurse, occupational therapist, speech language pathologist, neuropsychologist, social worker, and recreational therapist. All team members participate in formulating a treatment and discharge plan, working together to attain collective goals of reducing patient disability and in educating and training the patient and family in preparation for return home. Importantly, patients must also shift from being passive recipients of medical treatment in the acute setting to being active participants in their own therapy to maximize their neurologic recovery.

Physician

The physician, as team leader, defines the type and prognosis of the neurologic disorder, sets realistic treatment goals, and coordinates the rehabilitation services. A major role of the physician is to optimize patient engagement in therapy through management

of medical issues (eg, orthostatic hypotension, depression, pain, constipation or incontinence, infection, nutrition, and hydration). With the team, the physician reviews progress toward attaining functional goals that allow the patient to return home. Roadblocks, alternative strategies, and discharge dispositions are discussed at weekly team rounds. Postdischarge plans for home care and outpatient therapy are coordinated with the patient and family.

Rehabilitation Nursing

Rehabilitation nurses provide general medical and more targeted nursing for patients with neurologic dysfunction. A major nursing focus for the neurologically impaired patient is prevention of pressure ulcers due to immobility and management of bowel and bladder incontinence (see the following section). In the inpatient setting, the nurse helps incorporate skills learned in therapy into the patient's daily routines. The nurse also educates the patient and family in medication administration, self-catheterization, and skin care.

Physical Therapy

Physical therapy focuses on bed mobility, transferring to chair or toilet, ambulating and/or wheelchair mobility, and stair climbing. Techniques and orthotics are chosen to maximize safe and independent mobility; to optimize energy efficiency; to prevent decubitus skin ulcers, tendon contractures, and falls; and to enhance motor recovery. Limitations in mobility and sensorimotor function are addressed by strengthening exercises, gait and balance training, and stretching. The PTs also concentrate on musculoskeletal and orthopedic injuries. Typical problems associated with neurologic injury include musculoskeletal pain, muscle spasm, joint pain, heterotopic ossification, and contractures.

Leg and trunk weakness, impaired postural reflexes, ataxia, proprioceptive loss, and visuospatial neglect may all interfere with ambulation and are actively managed. Bracing, assistive devices (eg, cane, walker), and a wheelchair are used as compensatory strategies for safe completion of ADLs. The feasibility of restoring ambulation depends on diagnosis, severity of neurologic impairment, and comorbid conditions (eg, sarcopenia in elderly patients). For example, for most stroke survivors, ambulation is usually ultimately achievable through rehabilitation even if nonambulatory in the acute phase, often with the use of an ambulatory aid such as a cane and/or a brace for the ankle. When ambulation is not possible, such as for many individuals with spinal cord injury, mobility is attained through training in the use of a wheelchair of the correct size and height, occasionally employing a special seat to prevent skin breakdown or cushions for trunk support. For individuals who cannot self-propel a manual wheelchair, a power wheelchair can often be used for independent mobility. Exoskeletal-powered leg braces have been developed, which can provide limited walking ability for individuals with paraplegia (Fig. 157.1), although cost and device limitations remain barriers to widespread adoption at present.

FIGURE 157.1 Exoskeletal robotic leg braces for individuals with paraplegia. (Courtesy of ReWalk.)

Occupational Therapy

Occupational therapy (OT) focuses on restoring ability to perform ADLs and addressing limitations in the patient's occupational and social role caused by neurologic injury. The OTs treat patients with the goal of enabling patients to return to home, community, and work. Typically, OTs concentrate on impairments affecting the use of the arms and hands, such as weakness, sensory loss, ataxia, and abnormal tone. Improving motor skills is only one of the important components in enhancing performance of ADLs. The OTs also address impaired attention, judgment, cognition, and memory; visuospatial neglect; and apraxia. Training focuses on restoring upper extremity functional skills that are important for self-care at home and autonomy in the community. If necessary, adaptive aids are used to increase the use of the impaired arm and hand, such as hand and wrist orthoses, reachers, Velcro closures, and built-up utensils. When the impairment is unilateral and severe, an occupational therapist may select adaptive equipment and train the patient and family to compensate. Advanced programs may include learning special one-sided techniques, such as driving with the left hand and foot.

The OTs also optimize safety and functionality in the home environment by training the patient and the family in use of adaptive equipment (eg, tub benches, elevated toilet seats, ramps, grab bars, safety rails).

Speech, Language, and Cognitive Therapy

The speech-language pathologist (SLP) focuses on dysphagia (see the following section), dysarthria, aphasia, and cognitive dysfunction in the neurologically impaired patient.

Treatment of dysarthria aims to improve intelligibility and includes methods such as slowing and exaggerating articulation, increasing breath support, and pacing speech rate. For aphasia, the SLP identifies areas of strength and weakness in receptive and expressive language. Areas of strength may then be used for compensatory purposes, such as using better preserved written expression in lieu of verbal expression. Therapeutic approaches vary widely but can employ visual and verbal cueing, melodic intonation (using preserved singing ability to facilitate speech), and constraint-induced language therapy (limiting the use of compensatory actions by the patient, such as pointing at objects, "forcing" the patient to verbally express themselves). For example, use of visual imagery as an internal cue may help to overcome the word blocking of expressive aphasia.

For cognitive rehabilitation, speech and occupational therapists collaborate on program development and implementation, and all members of the rehabilitation team contribute. Neurobehavioral impairments and how they interfere with function are first identified. Diffuse brain injury may affect several cognitive domains, and the therapeutic approach is tailored to the nature and complexity of the symptoms. For example, inattention and distractibility may preclude participation in group activities such as business meetings, or memory impairment may lead to failure at school. In diffuse or multifocal brain injury that impairs attention, behavior, cognition, and language, it is necessary to provide a structured program that minimizes distractions by controlling the noise and activity in the environment. Strategies are used to help compensate for impairments across multiple cognitive domains. For example, memory cues help to improve retention of techniques learned in physical therapy or OT; breaking a task into individual steps and then teaching one step at a time helps to overcome attentional and constructional problems. Finally, the SLP educates the patient and family about aphasia and other cognitive problems. This is essential to reduce frustration with impaired communication, memory, and abnormal behavior.

Psychology and Neuropsychology

Psychologist and neuropsychologists concentrate on the mood, behavioral, and cognitive problems that occur after injury to the brain. Neuropsychologists may perform detailed neuropsychological testing of the patient to identify cognitive and affective disorders and make therapeutic recommendations to the team. Psychologists and neuropsychologists may also counsel the patient and family in the management of their disorders.

Social Work

Social workers identify concrete resources that will enable the patient to succeed at home, such as finances, availability of caregivers, and community services. They provide counseling, support, and education to the family, who often take on a caregiving role for the patient. Social workers or case managers may directly interact with the patient's insurance provider, supplying medical updates and obtaining authorizations. They also coordinate home services and delivery of adaptive equipment and facilitate discharge planning.

Recreational Therapy

Recreational therapy focuses on the patient's social and emotional health through use of enjoyable recreation, with a goal of reintegration into the community. Group activities such as games, karaoke, gardening, and arts and crafts encourage socialization and engage patients physically and cognitively.

SPECIALIZED NEUROLOGIC AND MEDICAL MANAGEMENT

Dysphagia

Swallowing is a complex act involving voluntary and involuntary muscles including facial, lingual, masticatory, pharyngeal, esophageal, and respiratory muscles. Neurologic disorders that disturb coordinated contraction and interaction of these muscles can cause dysphagia and, secondarily, dehydration, malnutrition, aspiration pneumonia, and airway obstruction. Dysphagia evaluation is indicated for patients who have any of these complications; who report coughing, choking, or nasal regurgitation while eating; who are dysarthric; or who have a disease commonly associated with dysphagia, such as motor neuron disease, myasthenia gravis, or brainstem stroke. Dysphagia is identified with bedside testing and with video fluoroscopic or fiberoptic endoscopic evaluations of swallowing. Therapeutic approaches include altering the consistency of foods and thickening liquids, using head repositioning strategies such as a chin-tuck technique, and reducing the rate and amount of intake.

Bladder and Bowel Dysfunction

Loss of control of bladder or bowel emptying is commonly associated with several neurologic disorders and should be addressed by comprehensive neurorehabilitation programs. The cause of impaired bladder emptying or sphincter incompetence, and therefore the treatment, depends on the site of the neural injury. Evaluation includes clinical observations about incontinence and retention; addressing communication and mobility contributors (eg, difficulty in communicating toileting needs or reaching the bathroom); search for nonneurologic factors, such as infection or mechanical problems, particularly urethral obstruction by prostatic enlargement; and cystometrographic measurements of bladder and sphincter functions. The neurorehabilitation nurse plays a crucial role in the treatment of bladder and bowel disorders, including implementation of voiding programs and training patient and family to use urethral catheters.

The goal of bladder rehabilitation is to allow the bladder to fill under low pressure to a volume of 200 to 300 mL, then empty, whether volitionally or mechanically and without incontinence between emptying. Incontinence characterized by bladder hyperreflexia, in which the bladder contracts at low urine volumes and voluntary inhibition of bladder contraction and sphincter relaxation fails, commonly complicates cerebral, particularly frontal lobe, injury. Lack of awareness or indifference may impede achievement of continence, but neurologic recovery usually reduces incontinence. Prompted voiding at 2-hour intervals contributes to regaining continence. Detrusor-sphincter dyssynergia, in which dissociated bladder contraction and sphincter relaxation results in the bladder contracting against a closed sphincter, is usually a consequence of lower brainstem or spinal cord lesions. Bladder emptying, if it occurs at all, is incomplete and occurs at high vesicular pressure. Treatment includes bladder antispasmodic drugs and intermittent catheterization at 4- to 6-hour intervals. Hydronephrosis, renal failure, and bladder wall hypertrophy with consequent volume loss are potential complications of a chronically high-pressure bladder. Conversely, peripheral nerve diseases involving the nerves innervating the bladder may cause bladder flaccidity. Bladder emptying, at low pressures, is incomplete, and incontinence occurs between voluntary voiding. Cholinergic agents (e.g. Urecholine) may improve emptying, but intermittent catheterization is often necessary.

Neurologic disorders leading to immobility, decreased fluid access and intake, and loss of cortical control over rectal sphincters may cause severe constipation or impaction. Prevention combines a high-fiber diet; adequate hydration; stool softeners; and regularly scheduled evacuation using suppositories, enemas, and/or digital rectal stimulation. Bowel incontinence can also be lessened by scheduled toileting, providing regular clearance of the rectal vault.

TABLE 157.1 Morbidity in Rehabilitation

Preventable Morbidities	Common Preexisting Comorbidities Requiring Regulation	Secondary Effects
• Deep vein thrombosis • Recurrent or progression of stroke • Aspiration pneumonia • Urinary tract infections • Fecal impaction • Pressure ulcers • Falls • Dehydration • Malnutrition • Influenza or pneumococcus infection • Accelerated osteoporosis	• Hypertension • Diabetes • Osteoarthritis • Coronary artery disease • COPD • Peripheral vascular disease • Substance abuse • Impairments of hearing and vision • Poor dentition • Sleep apnea	• Partial or generalized seizures • Depression • Cognitive impairment • Intracerebral bleeding • Hydrocephalus • CSF leakage • Autonomic dysreflexia • Heterotopic ossification • Surgical site complications • Infection • Fever • Pain • Musculoskeletal injury

Abbreviations: COPD, chronic obstructive pulmonary disease; CSF, cerebrospinal fluid.

Medical Care

An important component of rehabilitation neurology is the prevention of secondary complications, the optimized management of existing comorbidities, and the early recognition and treatment of known complications or effects of injury (Table 157.1). Comorbidities are extremely common and are often dysregulated or exacerbated by the changes in activity, diet, and medications that occur after sudden neurologic injury. For example, poststroke rehabilitation has goals of gradual control of elevated blood pressure, proper control of diabetes, dyslipidemia management, appropriate administration of anticoagulation or antiplatelet agents, and counseling on lifestyle changes (eg, cessation or reduction of alcohol and tobacco use, increase in exercise) LEVEL 1.[6] Low molecular weight heparins are used to prevent deep vein thrombosis; appropriate oral consistencies are chosen to minimize the risk of aspiration and to maximize nutrition and hydration; and preventative measures are put in place to minimize the risk of falls. Poststroke depression is common and can be effectively treated with antidepressant medications such as citalopram or other selective serotonin reuptake inhibitors.

The goal of the physician is to optimize the medical management and lifestyle changes that will reduce comorbidities and secondary effects of brain injury and to coordinate with the patient's primary physician for continuation of optimum outpatient care.

158 End-of-Life and Palliative Care in Neurology

Tobias Walbert, Fred Rincon, and James M. Noble

KEY POINTS

1. Neurologic disease trajectories, ranging from rapid to slowly progressive, and the diseases themselves, often dictate urgent treatment decisions and involve end-of-life care.
2. Palliative care focuses on the alleviation of suffering of any kind and is relevant to all stages of neurologic disease.
3. Advance directives and related orders formalize a group of key discussions held by neurologic patients, families, and their physicians and help shape the course of neurologic care when patients cannot make decisions on their own any longer.
4. Conversations about end-of-life care should happen early in the course of neurologic disease and complement other discussions involving advance directives.
5. Some neurologic diseases prevent patients from engaging in advance directive discussions and introduce potential challenges related to surrogate decision making.
6. Decisions to withdraw or withhold life support may be triggered by the need to perform a tracheostomy and gastrostomy if continued aggressive support is pursued.
7. Hospice services permit the transition of care from being focused on control of neurologic disease to the alleviation of patient suffering and quality end-of-life care.

INTRODUCTION

Disease trajectories and survival in neurologic disorders are highly variable person to person and make overall predictions challenging. The recent development of disease-modifying therapies has been life changing for many persons with some chronic neurologic diseases. For example, most forms of multiple sclerosis have effective therapies, which slow or even stop progression, and some young children with spinal muscular atrophy are now able to achieve major motor milestones previously thought impossible. But unfortunately, many neurologic diseases have not yet benefitted from major breakthrough therapies.

Although neurogenic causes of death are central to this text, with newer treatment options/technologies, patients may live longer with chronic neurologic diseases and thus die of nonneurologic causes such as coronary disease or nonneurologic malignancies, etc. Conversely, increasingly effective therapies for nonneurologic diseases, particularly cardiac and oncologic innovations, have prolonged life and permitted patients to age into periods of life more prone to be impacted by neurologic disease. With new treatments, new clinical conundra have emerged, such as definitively treating a critical medical problem, which in turn leads to longer lifespan but potentially mostly during periods of lower quality of life such as late and terminal stages of neurodegenerative disease. As discussed throughout this text, supportive care for current needs and advance care planning are essential parts of providing effective neurologic care.

Neurologic diseases occur over a wide range of timeframes, ranging from sudden life-changing illness to chronic or even life-long disease. Some diseases are chronically progressive, some are static, and some precipitously worsen. Because neurologic diseases present with a wide array of clinically localized presentations, how a patient progresses and dies is also highly variable. For example, persons with central brain diseases tend to face complications following focal or diffuse cerebral problems including hemiparesis, seizures, parkinsonism, or complications of dementia. Persons with parkinsonian, spinal cord, and neuromuscular diseases face challenges with mobility. Both central and peripheral diseases are often affected by a common final pathway of complications stemming from becoming immobile and bedbound, including deep vein thrombosis, decubitus ulcers, recurrent dysphagia and aspiration, failure to thrive with critical dehydration, and recurrent infections. Many persons with severe brain disease will be unable to direct others who provide care to make the right decisions for them. Early engagement in advance care planning and anticipatory support are necessary for all persons facing neurologic disease and are necessarily tailored to each person's specific needs.

Disease Trajectories

Four illness trajectories are seen across neurologic diseases, and often, they co-occur within diseases. These can be broadly categorized as the following:

- *Immediate decline* occurs over the course of minutes to hours such as in acute ischemic stroke and intracranial hemorrhage leading to intensive care unit level care and sometimes herniation and brain death (covered in Chapter 20).
- *Subacute decline* occurs over the course of days to weeks. Examples of subacute decline include rapid tumor expansion or persons with amyotrophic lateral sclerosis (ALS) nearing a critically impaired level of functional breathing capacity.
- *Chronic progressive decline* is seen in diseases occurring over years. Examples include neurodegenerative dementias and

movement disorders, childhood neuromuscular disease, and progressive leukoencephalopathies. Even within chronic diseases, the pace of change may differ over periods of time and may accelerate in later stages.

- *Episodic decline* is marked by exacerbations of illness over time and can be superimposed on those facing ongoing subacute or chronic progressive decline. Episodic decline may be seen in patients facing a precipitous course but may not be as clinically obvious. Episodic declines can be seen in multiple sclerosis whereby a new inflammatory flare leaves a new and sometimes critical neurologic deficit. Other examples include treatment refractory seizures complicating a brain tumor course or a fall with hip fracture complicating a more chronic disease such as dementia.

All of the above presenting or dominant trajectories may enter some period of stasis or even recovery, depending what therapies may be available to treat the underlying or most acute problem. Based on the variability of disease progression, different approaches to palliative care and end-of-life planning might be necessary. The underlying considerations on how to approach these issues are discussed in this chapter.

PALLIATIVE CARE

Palliative care is defined by the World Health Organization as "an approach that improves the quality of life of patients and their families, facing the problem associated with life threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual." Palliative care can begin at any phase of disease but may be increasingly engaged in later stages of a disease course. Palliative care is often delivered simultaneously to disease-modifying therapies in neurologic disease. For example, in multiple sclerosis, immunomodulatory treatments alter the course of disease, preventing or minimizing the risks of additional attacks. Simultaneously, palliative therapies may be used to improve symptoms of spasticity, pain, or urinary dysfunction and alleviate suffering.

Palliative care delivery is based on a multidisciplinary team of physicians, nurses, and other specialists who work together with the neurologist to help with symptom management and advance care planning for patients facing a life-threatening neurologic disease. As such, multidisciplinary neuropalliative care is dynamic. Although traditionally thought of as being provided in the inpatient setting, neuropalliative care is central to treatment in ambulatory settings. Over the recent years, the subspecialty of neuropalliative care has been evolving. Whereas hospice care focuses on end-of-life care, palliative care can be initiated at any stage of the disease trajectory and is provided concurrently to neurologic treatment. This palliative approach in neurology can accommodate the evolving needs of the patient and caregivers. Although needs may differ patient to patient and between specialties, regardless of the underlying disease, advance care planning and engagement in palliative care should be initiated as early as possible, including prior to crisis episodes and well before end of life. Traditional models of palliative care delivery tended to involve palliative care when acute needs arose, whereas current approaches and guidelines encourage the early integration of palliative care along with episodic engagement as needs arise (Fig. 158.1).

FIGURE 158.1 **A:** Historic and least favorable model of late involvement of palliative care services. **B:** Model showing early and progressively increasing involvement of palliative care services. **C:** Model of dynamic involvement of palliative care services following specific trigger points. A combination of models **B** and **C** are most often associated with favorable outcomes. This graphic itself was reproduced from Bede P, Hardiman O, O'Brannagain D. An integrated framework of early intervention palliative care in motor neurone disease as a model to progressive neurodegenerative diseases. (From Hogden A, Foley G, Henderson RD, James N, Aoun SM. *J Multidiscip Healthc*. 2017;10:205-215.)

ADVANCE DIRECTIVES AND CARE PLANNING

Advance directives (also known as *living wills*) are legal documents that patients complete to express their wishes and guide their designated health care decision makers to direct care in the event they are no longer capable of making their own health care decisions. These documents appoint a surrogate decision maker (health care proxy or medical power of attorney) to make decisions at some future time and also specify the individual's health care preferences. The process of creating such a care plan is called *advance care planning* and is considered an ongoing conversation between the patient, care givers, and health care providers with the goal of extending patient autonomy. The content of advance directives can be narrowly focused on decisions around code status or decisions focused on do not resuscitate (DNR), do not intubate (DNI), combined DNR/DNI, or determination to allow natural death. Also included in advance care planning are decisions regarding artificial support of nutrition and hydration, including surgical placement of enteral tubes for feeding in the form of a percutaneous endoscopic gastrostomy or percutaneous endoscopic jejunostomy feeding tube. More recently advance directives have embraced a holistic approach, supporting how the patient would like to die, including aesthetic preferences and measures aimed at personalized comfort. How practical these measures may be is highly dependent on the location and context in which a person becomes ill, available resources, and availability of others to enact certain components of the plan.

Shortcomings of advance directives might be that (1) the health care provider may not find instructions that clearly guide

certain treatment decisions and (2) the ethical argument that a person may not be able to predict his or her own reaction if faced with a disability. However, advance care planning and completion of an advance directive are associated with care closer to patient preference, greater use of hospice, less intensive care use at the end of life, and bereaved family members reporting fewer concerns with communications.

Neurologic disease introduces unique challenges to advance care planning, particularly when meaningful cognitive or behavioral changes are a central part of the disease or in pediatric neurologic diseases. For persons with neurologic disease with recognized progressive cerebral disease, such as neurodegenerative disorders and brain tumors, advance care planning should engage the patient as early as possible due to expected future impairment in decision making. Doing so can allow the patient to provide meaningful input, which provides guidance to family members. Even when documentation is not completed by the time decisions need to be made, discussions held between patients and family can provide important guidance both through progression and at critical times.

Some persons may never engage in advance care planning discussions, which may only be introduced at a time after the person with neurologic disease can help guide treatment decisions. This may be the case when there is a delay in seeking care or when a neurologic disease is suddenly declared such as in major stroke or a patient with unrecognized metastatic cancer presenting with status epilepticus. Whether a patient is obviously unable to engage in important medical decisions such as in critical illness, or when facing a moderate degree of cognitive decline, concerns may be raised about the ability for a patient to participate in such discussions.

TABLE 158.1 The Informed Consent Process

Components	Example
Verifying that the patient has decision-making capacity	This component verifies that the patient has insight into the proposed procedure or research. A bedside evaluation assessing if the patient can (1) understand the information; (2) understand the current situation and its consequences; (3) rationally consider information in light of one individual's values; and (4) retain the information given, analyze it, and make an informed decision.
Full disclosure	This component is designed to explain the risks and benefits, ratio, complications, and alternatives of the procedure or research. Without disclosure, voluntary choice and competence cannot be properly exercised.
Understanding	In this component, the agent verifies that the patient understands fully the risks and benefits, specifically if the ratio (risk/benefit) is in favor or not.
Voluntary choice	In this component, the agent verifies that there is deliberate informed consent. The informed consent process should be guided by the freedom to act voluntarily without coercive forces or due influence.
Formal authorization	In some jurisdictions, a written document is necessary to fully execute the procedure or research for which the subject has been asked to consent. This should include a statement of risk/benefit and potential complications and alternatives and the signatures of the health care provider, patient or surrogate, and in some instances, a witness.

Orders for Life-Sustaining Treatment

Several recent efforts have worked toward standardizing how advance care plans are enacted, particularly in the final stages of illness and life, and across multiple care settings, recognizing that critical treatment decisions are made outside of a hospital, where traditionally DNR/DNI plans were enacted. Started in 1991, the Physician Orders for Life-Sustaining Treatment (POLST) began as an initiative to translate goals for care at the end of life into medical orders that follow the patient across care settings with one of the goals being to create legal certainty. POLST programs have been encouraged in most states and become an enduring part of a patient's medical record. Related programs and initiatives, or simply renaming of POLST in certain areas, include Medical Orders for Life-Sustaining Treatment (MOLST; regionally in Northeastern United States and focused on out of hospital DNR/DNI), Medical Orders for Scope of Treatment (MOST; several states), Physician Order for Scope of Treatment (POST; several states), Do Not Resuscitate Order/Clinician Orders for Life-Sustaining Treatment (DNR/COLST; Vermont), and Transportable Physician Orders for Patient Preferences (TPOPP; Kansas and Missouri).

Informed Consent and Decision Making

The concept of informed consent originates from the notion that individuals are autonomous. Rational individuals with decisional capacity, or competency in legal terms, are uniquely qualified to decide what is best for them. It also means that people should be allowed to do what they want, even if doing so involves considerable risk or would be considered foolish by others. This of course is supported only if the individual's decision does not infringe on the autonomy or welfare of another individual (**Table 158.1**). When a patient is found not to have decision-making capacity, the health care provider needs to identify an alternate means to guide treatment decisions. For patients facing treatment decisions, this also means that the clinician must identify an alternate means to obtain consent, such as when considering invasive procedures. The options in these cases are (1) to use guidance provided in a written advance directive or (2) in the absence of an advance directive, the physician must seek the substituted judgment of a proxy or surrogate authorized by the jurisdictional law.

Several principles provide guidance for care in the absence or surrogate decision makers or a patient not providing such direction. The first, *substituted judgment*, is the principle of making a decision for the patient that they would have made themselves if able to make decisions. Authorized surrogate decision makers help in decision making as the patient cannot themselves. These persons can be appointees by advance directive or durable power of attorney (for health care decisions), or as a health care proxy or an appropriate surrogate permissible by jurisdictional law. They are expected to make the same decisions as the patient would if the patient's capacity were intact and usually based on knowledge of the patient's general values and preferences. There are inherent flaws in this approach related to the poor accuracy of the proxy's ability to predict the patient's wishes, the inherent difficulty of making serious decisions for other persons may also

make proxies reluctant to participate in the consent process on any level. This can lead to increased reliance on the physician's expertise without fully considering the risks and benefits associated with an intervention.

Secondly, the *best interest standard* may be applied when other sources for care planning and consent are lacking. This is a legal exception invoked in emergency situations, in which the consent of a reasonable person to appropriate treatment is implied. The emergency doctrine of "implied consent" allows providers to deliver certain interventions that if not performed in a timely and typically urgent or emergent basis could potentially lead to increase morbidity and mortality. The requirements to meet the best interest standard for emergency situations are as follows: (1) The treatment in question represents the usual and customary standard of care for the condition being treated, (2) it would be clearly harmful to the patient to delay treatment awaiting explicit consent, and (3) patients ordinarily would be expected to consent for the treatment in question if they had the capacity to do so. This principle is also applicable in those cases when the burden of a therapy outweighs the benefits and the pain of interventions, which would make them inhumane. Despite widely held beliefs to the contrary, it is not necessary to obtain legal counsel before withdrawing life-sustaining therapy, although engaging a local ethics resource (such as a hospital consultative service) can be very helpful in some situations, particularly if there is any ambiguity raised in the case or concerns expressed by family. One of the shortcomings of using the *best interest standard* is the possibility of the health care provider being judged as paternalistic based on that person's inherent role to prevent evil or harm by promoting good and welfare for others.

END-OF-LIFE CARE

Neurologic diseases have been at the center of discussions on issues at the end of life. To this end, end-of-life conversations should be routine between health care providers and patients suffering progressive neurologic diseases. The American Academy of Neurology has set standards for the determination of death based on neurologic criteria, prediction of outcome in comatose survivors of cardiac arrest, and for the persistent vegetative state. Additional diseases such as ALS and Alzheimer disease have been the focus of debates about physician-assisted suicide (PAS). Health care providers practicing in neuro–intensive care units also face end-of-life discussions when withholding or withdrawing life-sustaining therapies.

Life-Sustaining Therapies

Aside from disease-modifying or life-extending pharmacotherapies, two treatments should be universally considered in the context of end-of-life therapies for neurologic patients. These include (1) mechanical ventilation and (2) artificial nutrition and hydration through enteral feeding. These therapies may be used with varying degrees of encouragement by physicians and acceptance by patients, depending on neurologic disease. For example, young children facing severe neuromuscular diseases are very likely to be offered these therapies due to age, intact cognitive abilities, and obvious emotional strain of forgoing life-sustaining therapies in a young person. Given the emergence of life-changing therapies in some neuromuscular diseases and previously untreatable or incurable diseases, hope for new disease-modifying therapies may encourage use further.

At the other end of the age spectrum, life-sustaining therapies are most often considered in the context of neurodegenerative disease. In the context of dementia, surgically placed enteral tube feeding as a life-sustaining measure has fallen out of favor by many but not all persons—physicians, patients, and caregivers alike. Given that in most cases, enteral feeds are introduced in the most advanced stages of disease, most but not all families recognize that enteral feeding at best extends time spent in advanced state without necessarily improving quality of life. Enteral feeding was historically offered at a point when aspiration risks had emerged, and it is now recognized that risks of oropharyngeal microaspirations and aspiration pneumonia are not substantively mitigated by placement of enteral feeding tubes. Moreover, once surgically placed, enteral feeding tubes are not without risk, including surgical complications, pain, and risk of accidental removal, either by an agitated patient or in the process of moving a patient. The concept of "comfort feeding" in end-stage dementia has emerged, whereby very small quantities of food are hand-fed so long as it is not obviously distressing. This approach serves an alternative to tube feeding and provides comfort to alleviate perceived hunger when the patient is attempted to be fed and further addresses a potential family perception that providing no artificial hydration or nutrition is equivalent to "no care" being delivered. Video-based decision support tools have proven useful in discussions with dementia patients and caregivers. Even in dementia, mechanical ventilation is rarely necessary unless a complication of another illness has occurred.

In other neurodegenerative diseases such as ALS, or other progressive neuromuscular disorders in which cognitive abilities are preserved, there may be a greater tendency to offer both mechanical ventilation and enteral feeding as life-sustaining measures. With the advent of assistive communication devices and importance of treating mood disorders associated with end-of-life care, in these diseases there is a recognition of potential for additional time spent with a measurably good quality of life and not just an extension of life.

Ineffective, Inappropriate, and Futile Therapies

Health care providers may often encounter clinical situations in which therapies may be ineffective at achieving certain goals. Health care providers may not know whether a therapy, in a particular neurologic condition, will be effective unless the therapy is trialed. In this case, it is always better to attempt a "trial of intervention" by setting up reasonable goals of care. This hypothetical action plan, devised as a decision tree with multiple iterative outcomes, can help in determining whether those goals can be achieved by ongoing reassessment and allowing the health care provider to find if the therapy is ineffective while maintaining good communication with a patient's families, friends, and surrogates. This approach allows the health care team to withdraw an ineffective therapy rather than withhold a potentially beneficial treatment, limiting the chance for undertreatment and avoiding ethical dilemmas. It also allows for consideration of some scenarios whereby treatments may be capped. For example, in a patient who has already failed multiple chemotherapeutic agents and is facing more frequent, serious, and irrecoverable complications of disease, a plan can be implemented to offer no new therapies but permitting ongoing treatments to continue if they do not negatively affect the patient's quality of life.

Some other treatments may be considered inappropriate or inadvisable. Such treatments are characterized by extremely low likelihood of achieving the intended goal, minimally or potentially beneficial but extremely expensive, and of uncertain or controversial benefit. Finally, some other treatments may be labeled as futile. There is still controversy about the medical definition of futility, but in general, futile medical interventions serve no meaningful purpose no matter how often they are repeated. Therefore, a futile medical intervention is that for which there is de facto knowledge that it will not accomplish its intended goal. Characteristics of a futile therapy are that the intervention has no pathophysiologic rationale, that the intervention has already failed in the patient, and that the unintended effect occurs despite maximal treatment. Futile, inappropriate, or inadvisable cases are fortunately rare but very complicated from the ethical perspective, as they bring the values of the patient, surrogates, health care providers, and the society at odds. For this reason, resolution of these conflicts requires conscientious ethical analysis and a fair process that usually involves a multidisciplinary team and a bilateral or shared conflict resolution.

Withholding and Withdrawing

When facing withholding or withdrawal of medical interventions, ethical questions cannot be addressed successfully unless the probability of various outcomes is considered. To attain a balanced view of the impact of therapeutic decisions and the expected disability to the patient, the effort requires understanding of disease in question and a multidisciplinary team approach. Morally, there may be no difference between withholding and withdrawing life-sustaining therapies. However, patients, families, and health care providers have strong and divergent views. Some may feel comfortable with both situations, some may feel comfortable only when deciding not to start a therapy, but some may feel uncomfortable deciding when to stop that therapy. According to Miller and Truog, "What distinguishes withdrawing from withholding, is that in the former, the agent initiates the fatal consequence, as distinct from merely permitting it to continue without intervention to stop it." The distinction between withdrawing and withholding may cause feelings of reluctance but is morally irrelevant and can be dangerous. From the legal standpoint, the courts in the United States have upheld the concept that there is no difference between withdrawing and withholding. Both are medical decisions that entail a duty to inform the patient and his or her representative.

Death, Dying, and Hospice Care

According to the World Health Organization, health in its broader sense is defined as "a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity." Because this "state" is sometimes hard to achieve at the end of life, patients suffering terminal neurologic diseases should also have access to therapies that carry a different goal in mind: the relief of pain and suffering.

Hospice care is considered as palliative care in the last months to weeks of life, and patients may not be eligible for services unless there is a reasonable estimate that death will occur within the next 6 months. Clinical predictors have been developed for neurologic diseases with potentially long and sometimes unpredictable duration spent in severe phases of disease, including dementia and ALS. The primary goals are to relieve patients from suffering and focus on quality of life. Hospice care can be delivered in a variety of places, such as a hospital, free standing hospice unit, a nursing home, or increasingly at home. Although most Americans express their desire to die at home, relatively few actually die there, and many die in hospitals or nursing homes instead.

Although patients with neurologic disease and their families increasingly engage in hospice services, its use remains incomplete. Factors associated with hospice referral include physician comfort with discussing terminal events long enough in advance, difficulty in determining prognosis, and resource availability including financial and personnel (eg, family members' capacity to serve in a caregiver role if continuous care is not available). Several initiatives have encouraged advance care planning, including broad acceptance of free or low-cost legal documents around advance care planning.

Pain management is an important aspect of palliation. Some actions during palliative care aimed at controlling pain are morally and ethically acceptable and may have foreseeable but unintended and undesirable outcomes; the morality of the action depends on the morality of the intended outcome, not the unintended one. Several conditions must be met: (1) The action to be carried out must be morally or ethically acceptable or at least neutral, (2) the good effect must not depend on the undesired or bad effect, and (3) the good effect must be sufficient to justify the risk of the unintended outcome. Although it is not the intent of hospice care to hasten death, this principle makes it possible to administer sufficient analgesic and sedative medication to keep a patient comfortable even though the treatment will not prolong life. The principle of *double effect* is the basis of the hospice program (**Table 158.2**).

In certain circumstances, the burden of a neurologic disease at the end of life may be higher than expected. Certain patients may not achieve adequate relief of symptoms even with palliative care measures that usually include the titration of opioids. As defined by Broeckaert and Nunez-Olarte, "palliative sedation is the intentional administration of sedative drugs in dosages and in combinations required to reduce the consciousness of a terminal patient as much as necessary to adequately relieve one or more refractory symptoms." This is usually achieved by the use of benzodiazepines, propofol, and barbiturates. It is intended to achieve the relief of overwhelming symptoms when other conventional palliative care strategies have failed. The American Medical Association's Council on Ethical and Judicial Affairs has provided support for the use of palliative sedation at the end of life when (1) patients are in the final stages of their disease and are expected to die shortly, (2) conventional treatments have failed to control the symptoms, (3) consent has been obtained from the patient or surrogates, (4) a multidisciplinary team of experts have already assessed the patients' symptoms, (5) palliative sedation will not be used to solely existential experiences (anxiety, depression, feelings of isolation, etc), and (6) it will not be used to intentionally cause a patient's death.

Palliative sedation is usually reserved for the intensive care unit environment or for units designed to fulfill that purpose. Some ethicists have argued about the difference between palliative sedation and euthanasia. The difference lies in the concept of intent and the timing of the procedure. Palliative sedation is used to achieve a control of symptoms during the process of death (last resort), when other measures have failed, and exclusively in actively dying patients.

TABLE 158.2 Palliative Care Protocol During Withdrawal of Life Support

Steps	Procedures
Prewithdrawal of LST	• Meet with surrogates and family to discuss withdrawal of LSTs. • If patient is conscious, involve him or her in the discussion. • Prepare to discuss other issues such as organ donation. • Establish a time frame and additional needs: pastoral care, etc. • Document plan and discussion in the chart. • Discuss with clinical team. • Review LSTs to be withdrawn (ventilator, medications,[a] IV or enteral fluids, parenteral or enteral nutrition, pacemakers, IABPs, RRT, blood draws, etc).
Sedation/analgesia	
• Lorazepam	• If any, continue current infusion if patient is comfortable, then bolus same as hourly dose; may increase by 25%-50% OR • Begin with a bolus of 2.5-10 mg IV; may repeat boluses every 15 min as needed OR • Begin continuous infusion at 2.5-5.0 mg/h.
• Morphine	• If any, continue current infusion if patient is comfortable, then bolus same as hourly dose for signs of distress; may increase by 25% OR • Begin with a bolus of 10 mg IV and begin infusion at 5-7 mg/h. If discomfort, repeat boluses equal to hourly infusion dose and increase rate by 25%-50%.
• Fentanyl	• If any, continue current infusion if patient is comfortable, then bolus 25%-50% of the hourly dose and increase by 25%. OR • Begin with a bolus of 25-100 μg IV and begin infusion at 25-100 μg/h. If discomfort, repeat boluses 50% of hourly infusion dose and increase rate by 25%-50%.
Withdrawal of LST	• Adjust analgesia and sedation to achieve no distress before withdrawal of LST (see above). • Reduce or eliminate alarm settings and monitors. • Disconnect cardiac monitors. • Disconnect other monitoring devices (arterial lines, ICP lines, etc). • Disconnect supplemental oxygen. • Remove lines and enteral feeding tubes, if any. • Suction and control secretions if needed.
After death	• Inform family and surrogates about official time of death. • Allow family and staff to surround the patient. • Allow family to visit patient postmortem if they choose to. • Assist with postmortem decisions and complete pertinent paperwork. • Document a death note in the chart.

Abbreviations: IABP, intra-aortic balloon pump; ICP, intracranial pressure; IV, intravenous; LST, life-sustaining therapy; RRT, renal replacement therapy.
[a]Medications that can be continued to provide comfort are, for example, antiepileptics (seizures), antiemetics (rare), and skin or local oral care (glycerine creams, etc).

Refusal of Therapy, Physician-Assisted Suicide, and Euthanasia

A competent patient's refusal of therapy should be interpreted in the broader context of care and is increasingly recognized as not necessarily being suicidal. In 1983, the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research published its report entitled *Deciding to Forego Life-Sustaining Treatment*. The conclusion from the President's Commission was that decisions regarding health care, including the refusal or withdrawal of life-sustaining treatment, rest ultimately with the competent patient and should be exercised through the country's long tradition of procedures for informed consent. On the other hand, refusal or withdrawal of therapies by surrogates on behalf of incompetent patients that remain conscious are ethically and legally permissible as long as there are written statements or in accordance with the patient's "wishes to the extent known." In the absence of these, the decision-making process is based on the patient's best interest.

Several countries as well as some states in the United States have legalized PAS. Although not universal, many locations which have permitted PAS, require patients to be at least 18 years of age, have the ability to communicate regarding health care issues, and be diagnosed with a terminal disease with 6 months or less of life expectancy (confirmed by two independent physicians). In the setting of PAS, a physician may prescribe medications to be used by a patient for the purpose of suicide. However, at least in the United States, the physician may not actually administer the drug. Neurologic diseases generate problems for PAS. Patients may be incompetent and unable to give consent at the time of intended drug administration, even if they were competent when forming previously expressed wishes. Other patients may lose the use of their hands from motor neuron diseases such as ALS. Under these circumstances, the patients themselves cannot fill the prescription and take the drug; someone else must assist them physically, which would be considered as euthanasia and is unlawful in the United States. PAS continues to be a highly debated topic with increasing public acceptance.

If in compliance with a patient's request a physician administers a lethal drug by injection or other means, the act is euthanasia, which is illegal in the United States. In euthanasia, the health care provider intends the death of the patient. In doing so, the health care provider selects the type of drugs and doses that are lethal by all objective measures. In the process, the health care provider administers the drug and causes unconsciousness and cardiac arrest. Only if the outcome is achieved, the health care provider can conclude that the intervention was successful. These contrast with the objective of palliative sedation and palliative care, where the intent is to relieve otherwise unmanageable symptoms (principle of double effect, as detailed earlier in this chapter).

The public, physicians, and courts have had difficulty separating refusal or discontinuation of therapy, which are legal, from assisted suicide and euthanasia, which are not, at least in the United Sates. The distinction between PAS and euthanasia is the most controversial of all. At present in the United States, palliative care and palliative sedation are permissible but PAS at the discretion of the states. In some areas where euthanasia is legal, further studies have suggested its use may at least in part be related to inadequate palliative care.

Other Neurologic Issues With Death

Neurologic diseases are often underrecognized as being immediate contributors to death, or even when recognized, may not be counted as such. The accuracy of neurologic causes of death is highly variable as captured by death certificates, with dementia being the most undercounted. Across multiple American studies, these discrepancies may be more apparent among race-ethnic minority groups, and likely reflect myriad issues in health care, ranging from available accurate information to appropriate access to care to stigma of certain diseases.

Processes involving organ and tissue donation are often standardized in health care settings and remain relevant to many persons with nontransmissible neurologic disease. Complementing donation programs are tissue research programs, but these are seldom discussed in advance of or at the time of death. Although autopsies have become increasingly uncommon over the past century, major research initiatives have grown and are underway to better understand neurologic disease as well as normal neurologic aging. Brain and spinal cord autopsy repositories have proven invaluable for insights into neurodegenerative disease and further tissue-based research initiatives are underway in the United States to cover a broader age and disease spectrum. Research referral networks have been implemented in the United States, supporting multiple neurologic disease groups, and have helped reduced geographic barriers to engaging in research, including after death. Discussions of neurologic tissue donation for research should be encouraged as part of advance care planning discussions, particularly if patients have experience or expressed interest in research or other organ donation programs.

CONCLUSION

The issues discussed here are among the most controversial in modern life. Consensus is not easy to achieve, views are changing, and current practices are likely to change as well. Already, pain control and palliative care have come to the fore and provide effective alternatives to assisted suicide. Documenting the preventive value of palliative care is a challenge for all concerned. Legal changes may be anticipated but do not seem imminent.
